Introduction

BY MAC FELLANDER

In 1912 LE DAMIANY described a manoeuvre by which unstable hips in the newborn could be revealed (*segno de ressauf*). Many years elapsed before the important discovery led to early treatment of hip dislocation. ORTOLANI in 1935 was the first to use this abduction manoeuvre (*segno dello scallo*) as a clinical method of early diagnosis and to carry out systematic early treatment. For a long time little attention was paid to Ortolani's works both in Italy and elsewhere.

In Sweden PALMEN introduced Ortolani's method in 1950 and soon succeeded in getting the National Board of Health to recommend in a circular letter of 1957 this method as a routine procedure for early diagnosis in all the maternity units in Sweden. Since then virtually all newborn babies are examined for hip dislocation. In a thesis of 1961 Palmén reported data from his own series as well as figures for the incidence in Sweden.

In 1952 VON ROSEN started systematic examination of newborn in the town of Malmö and he has published several reports of his results (1956, 1959 and later). His papers and his contributions in this field have received great attention in Sweden and in other countries.

Thus in Sweden we have now experiences from a 10-year period of nationwide early diagnosis and treatment of unstable hips. The Swedish Orthopaedic Association believes that the time has come for discussing this question generally and has therefore asked for reports from some of those who have devoted special interest to these problems.

The symposium comprises submitted papers and contributions to the discussion as well as free discussion.

Preluxation of the hip in the newborn

The diagnostic work in Sweden during the years 1953-1966

BY KURT PALMÉN FALKÖLING

As I was unable to accept the invitation to the symposium but was later asked to contribute to the discussion, I will first give a short account of the diagnostic work in Sweden. Since the beginning of the 1950's I have emphasized that the examination of the hip must be part of the routine examination of every newborn infant. I have then tried to follow these activities throughout the country and to study what effect the treatment of the newborn has had on the incidence of dislocation later treated in the orthopaedic departments. An account of the series up to and including 1960 will be found in my thesis published in *Acta Paediatrica* 1961. Since then the cases of hip dislocation from the orthopaedic departments diagnosed after the newborn period have been compiled for the years up to and including 1966. I will give some data from these series.

Diagnosis in the maternity departments

In 1953 examination of the hips was started at 26 obstetric departments with paediatric consultants and in 1956 examinations of the hips were performed at all the 45 departments with paediatric consultants. In 1962 a new drive was started to introduce the examination in all the small maternity units as well. In 1963 it was reported that examination of the hips of every newborn infant was made in 45 departments with paediatric consultants and in 55 smaller maternity units. About 110 000 or 99 % of the newborn babies in Sweden were delivered in these hospitals. Less than 1 % were born at home.

Hip examinations and the incidence of preluxation in the newborn in Sweden from 1953

	No. of infants born in departments where hips are examined	Percentage of all newborn in Sweden	No. of preluxation cases	Incidence of preluxation ‰
1953	33 000	31.0	32	1.0
1956	37 000	44.5	71	1.9
1959	48 000	51.2	216	4.5
1960	48 000	51.4	183	3.8
1963	110 000	99.0	115	1.1

In the first years the incidence of diagnosed preluxation (the term preluxation will be used here the cases of complete luxation in association with malformations are excluded) was about 1 per mill but had increased to 5.6 per mill in 1963. The incidence of missed cases was first higher but the high incidence for 1963 is in part very likely due to overdiagnosis. There would seem to be some geographical difference in the incidence for the whole country but figures of 15 to 20 per mill must be due to overdiagnosis. In the instructions for the technique of examination which were issued to the maternity departments in 1962 it was stated that only those cases in which the femoral head was clearly felt to be displaceable were to be recorded as positive whereas no significance was to be attached to snapplings and crepitations. The overdiagnosis suggests that many examiners were too ambitious and perhaps too afraid of missing a case. Some babies who at the first examination in the maternity department had shown suspected symptoms which were not verified by the orthopaedist at examination a few days later were included and treated for safety's sake.

Cases of dislocation missed in the newborn period

A survey of the cases of dislocation which were not diagnosed until after the newborn period and treated in all our orthopaedic departments shows a gradual decline of the incidence from about 110–120 cases each year before 1953 (8.5% diagnosed after the age of one year) to about 35 each year between 1959 and 1961 with a further decrease to an average of 25 cases in the last four years from 1963 to 1966. By routine examination of the hips in the newborn and the prophylactic early treatment our cases of later dislocation have been reduced by about 80% from the time before 1953.

Some cases are still missed at the examination in the maternity departments and to investigate the causes of this I have looked through the orthopaedic departments' records from 1962–1966 of cases of dislocation detected after the newborn period (here I wish to thank the heads of the departments for their kind permission). I will give some preliminary figures from this material (the survey is not yet completed).

127 cases of subluxation–luxation were not detected in the newborn period so far it is known that out of 113 of these babies 56 were born in a department with a paediatric consultant service. I was delivered at home and the rest were born in smaller maternity units with no paediatric consultants.

As more than 80% of the children in Sweden are born in departments with paediatric consultants the percentage of missed cases is much higher in the smaller units which lack paediatric consultants.

Out of the 127 cases 5 were cases of malformation arthrogryposis in 1

Preluxation of the hip in the newborn

The diagnostic work in Sweden during the years 1953—1966

BY KURT PÄRMEN FAIKÖPING

As I was unable to accept the invitation to the symposium but was later asked to contribute to the discussion I will first give a short account of the diagnostic work in Sweden. Since the beginning of the 1950's I have emphasized that the examination of the hip must be part of the routine examination of every newborn infant. I have then tried to follow these activities throughout the country and to study what effect the treatment of the newborn has had on the incidence of dislocation later treated in the orthopaedic departments. An account of the series up to and including 1960 will be found in my thesis published in *Acta Paediatrica* 1961. Since then the cases of hip dislocation from the orthopaedic departments diagnosed after the newborn period have been compiled for the years up to and including 1966. I will give some data from these series.

Diagnosis in the maternity departments

In 1953 examination of the hips was started at 26 obstetric departments with paediatric consultants and in 1956 examinations of the hips were performed at all the 15 departments with paediatric consultants. In 1962 a new drive was started to introduce the examination in all the small maternity units as well. In 1963 it was reported that examination of the hips of every newborn infant was made in 18 departments with paediatric consultants and in 85 smaller maternity units. About 110 000 or 99 % of the newborn babies in Sweden were delivered in these hospitals. Less than 1 % were born at home.

Hip examinations and the incidence of prelaxation in the newborn in Sweden from 1953 to 1966

	No. of infants born in departments where hips are examined	Percentage of all newborn in Sweden	No. of prelaxation cases	Incidence of prelaxation ‰
1953	37 000	31.0	32	1.0
1956	47 000	41.1	76	1.6
1959	68 000	57.2	211	3.2
1960	68 000	57.1	18	2.7
1963	110 000	99.0	61	0.6

In the first years the incidence of diagnosed preluxation (the term preluxation will be used here the cases of complete luxation in association with malformations are excluded) was about 1 per mill but had increased to 5.6 per mill in 1963. The incidence of missed cases was first higher but the high incidence for 1963 is in part very likely due to overdiagnosis. There would seem to be some geographical difference in the incidence for the whole country but figures of 15 to 20 per mill must be due to overdiagnosis. In the instructions for the technique of examination which were issued to the maternity departments in 1962 it was stated that only those cases in which the femoral head was clearly felt to be displaceable were to be recorded as positive whereas no significance was to be attached to snappings and crepitations. The overdiagnosis suggests that many examiners were too ambitious and perhaps too afraid of missing a case. Some babies who at the first examination in the maternity department had shown suspected symptoms which were not verified by the orthopaedist at examination a few days later were included and treated for safety's sake.

Cases of dislocation 'missed' in the newborn period

A survey of the cases of dislocation which were not diagnosed until *after* the newborn period and treated in all our orthopaedic departments shows a gradual decline of the incidence from about 110–120 cases each year before 1953 (87% diagnosed after the age of one year) to about 30 each year between 1959 and 1961 with a further decrease to an average of 20 cases in the last four years from 1963 to 1966. By routine examination of the hips in the newborn and the prophylactic early treatment our cases of later dislocation have been reduced by about 80% from the time before 1953.

Some cases are still missed at the examination in the maternity departments and to investigate the causes of this I have looked through the orthopaedic departments' records from 1962–1966 of cases of dislocation detected after the newborn period (here I wish to thank the heads of the departments for their kind permission). I will give some preliminary figures from this material (the survey is not yet completed).

127 cases of subluxation–luxation were not detected in the newborn period. So far it is known that out of 113 of these babies 56 were born in a department with a paediatric consultant service, 1 was delivered at home and the rest were born in smaller maternity units with no paediatric consultants.

As more than 80% of the children in Sweden are born in departments with paediatric consultants the percentage of missed cases is much higher in the smaller units which lack paediatric consultants.

Out of the 127 cases 5 were cases of malformation: arthrogryposis in 1

myelomeningocele in 1 myelomeningocele combined with club foot in 1 and club foot in 2

Out of 97 babies with known birth-weight 11 were prematures which is about three times the normal proportion of prematurity. In the group of newborn with preluxation, on the other hand the proportion of prematures was not increased. The probable explanation for the high incidence of prematures may be that many of the premature babies are immediately transferred to a ward for prematures or to a paediatric department and placed in an incubator, and their hips are not examined. The same explanation would be valid for a further two or three babies in the series who were immediately transferred to an infant ward because of asphyxia and who were in poor condition for a few days.

An interesting observation is that in five infants preluxation was suspected at the examination in the maternity department but X-ray was reported to have been negative. These infants were therefore left untreated. Dislocation was detected later in two of them not until their second year.

Thus in most cases it is probably the human factor that can be blamed for the failure of detecting dislocation at the examination in the newborn period. If congenital dislocation is not to be missed in the newborn the following measures would be important.

To make a careful clinical examination of the hips in every newborn infant not to forget those who immediately after birth are transferred to wards for prematures infant wards etc. and those born at home.

to give special attention to the hips in cases of malformation especially of the bones and joints such as arthrogyposis myelomeningocele dislocation of the knee-joint and club foot.

not to rely upon a negative X-ray examination

X-ray examination of the newborn

Preluxation in the newborn is a condition in which subluxation can be manifest when the leg is held for instance flexed adducted but reduction occurs when the leg is flexed and abducted to 80-90°. As I pointed out in 1961 the X-ray examination must be made with the baby's leg held in such a position that the examiner can feel that the head of the femur has been displaced (I disregard the cases of malformation with complete luxation) and much depends here upon the assistant who holds the baby during the examination. It is also important to ensure an exactly symmetrical position of the pelvis since any rotation from one side to the other or different degrees of lordosis will greatly influence the acetabular angle. I am not yet convinced that the X-ray examination provides any information in

addition to the clinical examination and believe that it can be omitted in the practical diagnosis of hip dislocation in the newborn

It is also obvious that errors can easily be made. Among the infants with dislocation referred to the orthopaedic departments between 1933 and 1966 I have found no less than 35 who showed clear or suspected symptoms in the newborn period but who were left without treatment because of negative X ray—and without careful checkings.

X ray examination later on—at the age of 5 or 6 months (earlier if there is a suspicion of subluxation) to check the effects of treatment and thereafter at for instance the ages of 1 and 3 years may be justifiable in order to follow the growth of the caputular nucleus and the acetabular roof

Treatment

Does every newborn infant with signs of preluxation need treatment and for how long? The displaceability of the femoral head and the click disappear within the first week of life in many cases within one or two days of birth in some cases. This means that the incidence will probably be higher if the examination of the newborn is made on the first day than on the third or fourth day of life. We know that there will be a normal hip development without treatment in many of these cases. Various authors estimate these mild cases at about 30 %. In some instances in which the baby lay with its legs flexed and abducted to 80—90° I postponed treatment for a few days. If the symptoms had disappeared by then I left the baby untreated. In other cases in which the baby tended to lie with its legs more adducted I applied a bandage which was removed after one or a few days. If by then the hip was stable at an attempt to displace the femoral head the bandage was not re-applied. The babies who had no or very short treatment were observed particularly carefully for the first few months. In a few cases the treatment had to be re-started but in the rest of these mild cases the hips developed quite normally. In infants with very marked displaceability and hip laxity I extended the treatment to about one month—lately seldom longer.

The short term treatment was used for the sake of trial and is not of course to be recommended as a practice to be followed generally. But I do believe that expectancy is justifiable in the mild cases in which displaceability of the femoral head is noted at examination on the first or second day of life but has disappeared when the baby is examined a few days later. In some clinics abroad they do not treat infants in whom the clinical symptoms disappear within the first week of life and consider that this policy works satisfactorily.

myelomeningocele in 1 myelomeningocele combined with club foot in 1 and club foot in 2

Out of 97 babies with known birth weight 14 were prematures which is about three times the normal proportion of prematurity. In the group of newborn with preluxation on the other hand the proportion of prematures was not increased. The probable explanation for the high incidence of prematures may be that many of the premature babies are immediately transferred to a ward for prematures or to a paediatric department and placed in an incubator and their hips are not examined. The same explanation would be valid for a further two or three babies in the series who were immediately transferred to an infant ward because of asphyxia and who were in poor condition for a few days.

An interesting observation is that in five infants preluxation was suspected at the examination in the maternity department but X-ray was reported to have been negative. These infants were therefore left untreated. Dislocation was detected later in two of them not until their second year.

Thus in most cases it is probably the human factor that can be blamed for the failure of detecting dislocation at the examination in the newborn period. If congenital dislocation is not to be missed in the newborn the following measures would be important.

To make a careful clinical examination of the hips in every newborn infant not to forget those who immediately after birth are transferred to wards for prematures infant wards etc. and those born at home.

to give special attention to the hips in cases of malformation especially of the bones and joints such as arthrogryposis myelomeningocele dislocation of the knee-joint and club foot.

not to rely upon a negative X-ray examination.

X-ray examination of the newborn

Preluxation in the newborn is a condition in which subluxation can be manifest when the leg is held for instance flexed—adducted but reduction occurs when the leg is flexed and abducted to 50—90°. As I pointed out in 1961 the X-ray examination must be made with the baby's leg held in such a position that the examiner can feel that the head of the femur has been displaced (I discuss the cases of malformation with complete luxation) and much depends here upon the assistant who holds the baby during the examination. It is also important to ensure an exactly symmetrical position of the pelvis since any rotation from one side to the other or different degrees of lordosis will greatly influence the acetabular angle. I am not yet convinced that the X-ray examination provides any information in

Instability of the hip in the newborn

Fifteen years experiences in Malmö

BY SOPHUS VON ROSEN Malmö

I presume that you are all more or less acquainted with the principles of diagnosis and treatment that have for many years been used at the department of orthopaedic surgery Malmö General Hospital and will therefore confine my paper to a few remarks and mainly on the results of treatment

The long term results are largely what I reported at the meeting of SICOT in Paris in September 1966. The material consists of all cases treated at Malmö in the years 1952—1960 and after-examined in 1965—1966. Of the some 21 000 infants born at the department of obstetrics in Malmö instability of the hip was diagnosed in 38 newborns with all together 68 unstable hips. The duration of follow up is given in Table 1

At the after-examination the following clinical and roentgenological observations were made

Clinically all the children except two were symptom free. One of these was a girl who from 12 months of age had developed spastic paraplegia with consequent defective abduction and reduced range of motion of both hips. The other was a 12 year old girl who complained of weakness of one of the hips (Fig 1 b)

Roentgenologically the children were examined for

- a) poor development of the acetabulum with subluxation and/or
- b) Perthes-like changes of the femoral head

a) Poor development of the acetabulum with subluxation

Apart from the above case with paraplegia two hips showed subluxation of the femoral head. The subluxation of one of these was only slight (Fig 1 a). The other hip was the one which felt weak on exertion. Here roentgen exam

*Table 1 Ages of Thirty six Children
Re examined*

Age in years	Number
6—9	25
9—13	11

Secondary bone changes

As regards the secondary bone changes discussed at the symposium much is still unclear. In some respects such changes probably depend upon the treatment and the time at which it is started. If treatment is started within the first week of life secondary bone changes develop very seldom. In the earlier part of my own series which now comprises about 130 infants there were two cases of necrosis of the head and a few of slight dysplasia. Among about 50 cases from 1961—1967 there were two of dysplasia which persisted at the age of two or three years.

The short-term treatment that I have tried for the last eight years was designed partly to study potential bone changes. The results are not yet ready for publication but I hope to be able to present them shortly.

Summary

In Sweden since 1953 hip examination is a routine at the obstetric departments. In the last years almost every newborn is examined (more than 99 % are born in hospitals). The incidence of diagnosed dislocation is about 5 per mill (there are still some overdiagnosis).

Thanks to this diagnostic work and the immediate treatment of the newborn the cases of later dislocation have been reduced from 110—120 cases yearly before 1953 to 25 in the last years. Still some cases are missed in the newborn most of them owing to the human factor.

Instability of the hip in the newborn

Fifteen years experience in Malmö

BY SOPHIE VON ROSEN MALMO

I presume that you are all more or less acquainted with the principles of diagnosis and treatment that have for many years been used at the department of orthopaedic surgery Malmö General Hospital and will therefore confine my paper to a few remarks and mainly on the results of treatment

The long term results are largely what I reported at the meeting of SICOT in Paris in September 1966. The material consists of all cases treated at Malmö in the years 1952—1960 and after-examined in 1961—1966. Of the some 21 000 infants born at the department of obstetrics in Malmö instability of the hip was diagnosed in 38 newborns with all together 68 unstable hips. The duration of follow up is given in Table 1.

At the after-examination the following clinical and roentgenological observations were made:

Clinically all the children except two were symptom free. One of these was a girl who from 12 months of age had developed spastic paraplegia with consequent defective abduction and reduced range of motion of both hips. The other was a 12 year old girl who complained of weakness of one of the hips (Fig 1 b).

Roentgenologically the children were examined for

- a) poor development of the acetabulum with subluxation and/or
- b) lighthouse-like changes of the femoral head

a) Poor development of the acetabulum with subluxation

Apart from the above case with paraplegia two hips showed subluxation of the femoral head. The subluxation of one of these was only slight (Fig 1 a). The other hip was the one which felt weak on exertion. Here roentgen exam

Secondary bone changes

As regards the *secondary bone changes* discussed at the symposium much is still unclear. In some respects such changes probably depend upon the treatment and the time at which it is started. If treatment is started within the first week of life secondary bone changes develop very seldom. In the earlier part of my own series which now comprises about 130 infants there were two cases of necrosis of the head and a few of slight dysplasia. Among about 50 cases from 1961—1967 there were two of dysplasia which persisted at the age of two or three years.

The short-term treatment that I have tried for the last eight years was designed partly to study potential bone changes. The results are not yet ready for publication but I hope to be able to present them shortly.

Summary

In Sweden since 1953 hip examination is a routine at the obstetric departments. In the last years almost every newborn is examined (more than 99 % are born in hospitals). The incidence of diagnosed preluxation is about 5 per mill (there are still some overdiagnosis).

Thanks to this diagnostic work and the immediate treatment of the newborn the cases of later dislocation have been reduced from 110—120 cases yearly before 1953 to 25 in the last years. Still some cases are missed in the newborn most of them owing to the human factor.

were unstable immediately after birth and that in each child one hip soon became stable despite the inadequate treatment

b) *Perthes like changes of the femoral head*

In none of the children were any Perthes-like changes of the femoral head observed. Only in one case did one side show a slight shortening and thickening of the femoral neck (fig. 1 c). Also that case belonged to the first eight. Treatment was started when the child was three weeks old and the hip in question remained unstable for eight months. The development of the other hip which was also originally unstable was normal.

Comments on diagnosis

The following questions deserve special attention

a) Table II shows the frequency of diagnosed cases during a 10 year period (1956—1965). The frequency varied considerably from year to year. I can not offer any satisfactory explanation for this variation. During the entire period the children were examined by the same team of paediatricians at the department of obstetrics and by the same roentgenologists and by the same orthopaedists.

A certain increase may be partly explained by the fact that during this period it was gradually realised how important it is to diagnose the condition early if satisfactory results are to be obtained with the consequence that all newborns were examined still more carefully. Another possible contributory reason is the increasing number of immigrants to Malmö from Yugoslavia, Italy and other Mediterranean countries.

b) *How many cases of instability of the hip have remained concealed at the*

a) Table II shows the frequency of diagnosed cases during a 10 year period (1956—1965). The frequency varied considerably from year to year. I can not offer any satisfactory explanation for this variation. During the entire period the children were examined by the same team of paediatricians at the department of obstetrics and by the same roentgenologists and by the same orthopaedists.

A certain increase may be partly explained by the fact that during this period it was gradually realised how important it is to diagnose the condition early if satisfactory results are to be obtained with the consequence that all newborns were examined still more carefully. Another possible contributory reason is the increasing number of immigrants to Malmö from Yugoslavia, Italy and other Mediterranean countries.

b) How many cases of instability of the hip have remained concealed at the

Fig 2 The first case missed at the routine examination at the maternity dept. A left sided dislocation indicated by the fact that the child limped when starting to walk was diagnosed at the age of 14 months. Closed reduction was performed resulting in a persistent subluxation at the age of 11 years.

department of obstetrics? Four all in girls in 1956 1960 1963 and 1966 respectively. The first case was discovered by the fact that the child limped when she began to learn how to walk (Fig 2 a). The parents were living elsewhere and the child was treated there with closed reduction and a plaster cast. Treatment appeared to offer no difficulties but the result was subluxation (Fig 2 b). The reason why this case was missed at the department of obstetrics might be that the child had asphyctic convulsions the day after birth and was therefore transferred to another department.

The second and third cases were also betrayed by a limp when the children began to walk in the beginning of the second year of life (Figs 3a and 1a). Both were treated at the department of orthopaedics in Malmö with closed reduction and Lorenz cast (plaster) in one case combined with adductor tenotomy. The results obtained were satisfactory in both cases (Figs 3b and 1b).

Fig. 3 The second case missed at the routine examination at the maternity department. X-ray at the age of 17 months showed a dislocation clinically indicated by a limp on the left side. After closed reduction and adductor tenotomy the joint has levelled satisfactorily.

It is not known why these cases were missed at the department of obstetrics; it must presumably be ascribed to the so-called human factor.

The fourth case was manifested by impaired abduction of both hips. The child was then one month old. Roentgen examination showed bilateral dislocation of the hip (Fig. 5). Treatment has proved difficult and is not yet concluded. The reason why this case was missed may have been that the femoral head might have been so highly dislocated already at birth that on manipulation it did not reach the same level as the lip (edge) of the posterior part of the acetabulum with the result that it was not possible to produce the reduction click. This assumption is strengthened by observations in another one of our cases. At examination at the department of obstetrics some slight atypical clicks of one of the hips were perceived in this case. To make

sure the child was referred to the roentgen department. Examination there revealed bilateral high luxation dislocation. Both hips could be reduced without difficulty and routine treatment resulted in a normal development of the hips.

Comments on treatment

Since 1956 all diagnosed unstable hips have been treated with the abduction frame constructed at the department of orthopaedics in Malmö. In my opinion the advantages of this frame are that when properly applied it holds the hips in reduced position and secondly it can be worn when the child is being washed and thirdly treatment of the child can without any difficulty be managed by the mother. The child is re-examined every 2–3 weeks at the outpatient department of orthopaedics where the frame is removed and the child is given a bath. Originally the appliance was made in only one size but now somewhat larger and smaller models are also available. One should take care that strong and lively children do not wriggle one or both legs out of the frame. In such cases which are uncommon the legs can be held more firmly in the frame by application of a few straps on the frame (Fig. 6).

The children's age at beginning of treatment during the 10-year period (1956–1965) are given in Table III.

The duration of treatment during the same period is given in Table IV.

The duration of treatment during the same period is given in Table IV.

Fig. 7 The last X rays of a girl at the age of 6 years which revealed an unusual degree of instability of the hips and of the pelvic junctions at birth. In spite of routine treatment in our frame followed by plaster for 1 month the left hip remained unstable up to the age of 10 months. The girl is clumsy with gynecomastia and an endocrine disorder is suspected.

Of the eight cases treated for more than 3 months four were treated for up to 1 month during the last month mainly only during the night. Two of the remaining four were the first to be treated with our newly constructed frame. At that time we were not sure how long the frame should be worn.

The case treated with plaster is of particular interest.

The patient was a girl with highly marked instability of the hips as well as of the pelvic joints. We had begun to wonder whether it was really necessary to keep the child in the frame for such a long period as three months and since both hips felt stable after 3 weeks the frame was removed. At follow up three weeks later the right hip was still stable but the other one was not.

Fig 8 A 1 m 1 1/2 y girl with bilateral instability in the hips at birth treated in our routine way. Both hips became stable within three months. At a follow up of the age of 10 months the right hip was unstable again with incipient dysplasia of the acetabular roof. After 8 months treatment in a large model of our frame the hip became stable and has developed normal. The general configuration of the girl became normal.

Fig 9 Another clumsy baby girl with hypermobile joints and bilateral instability in the hips at birth. With our routine treatment both joints became stable in the reduced position within three months. At a routine follow up at the age of 12 months the left hip was unstable again and X rays revealed dysplasia of the acetabular roof. At 4 months of renewed treatment in our frame the hip became stable and the acetabular roof developed satisfactorily. The general configuration of the girl is now (100) (100)

Fig 10 X ray of a recently treated girl with marked heredity for C.D.H. a cousin of the girl shown in fig 8 Both hip joints were highly unstable at birth. In spite of routine treatment for three months the right hip remained unstable. A plaster of Paris was applied for one month followed by a larger model of our frame up to the age of 9 months. The joint became stable and now seems to develop normally. There is a general hypermobility in all joints but otherwise the body build is quite normal.

unstable and remained so for 10 months despite immobilisation in plaster from 1 to 10 months of age. Both hips afterwards developed in a normal way (fig. 7). This girl has always been and still is rather clumsy and her joints are hypermobile. Some sort of endocrine disorder is suspected because of inter alia gynaecomastia.

An unusually crude body build and general hypermobility of the joints was also noted in the only two cases with recurrent instability of the hips both after primarily successful routine treatment. At the routine follow up of these girls at the age of 10 and 12 months respectively instability of one of the hips was noted with dysplastic acetabulum on the same side. Both girls were placed in a larger model of the frame, one for 8 months and the other for 1 month. When last examined roentgenologically the hips appeared practically normal. The outer shape had also become normal (figs 8-9).

The last case in which the course of treatment deviated from that in the others was, strangely enough, one of my grand nephews who was born in December 1966 with high severe instability of both hips, preponderantly on the right side. There is a strong heredity on the maternal side. The maternal grandmother and maternal aunt have dislocation of the hip and the child's cousin is one of the above-mentioned cases with recurrent instability. Treatment was started in the usual way and the left hip became stable after 6 weeks treatment. But the right hip was still unstable after 3 months and roentgen examination showed signs of acetabular dysplasia. The hip

was recently placed in Lorenz plaster and I hope and believe that also the hip will become stable and develop normally. The child has hypermobile joints but is of otherwise normal body build.¹

Summing up I believe that this method of treatment devised by us is adequate but one should be on the watch for children with crude body build and hypermobile joints and also for children with hereditary predisposition. It is possible that our treatment was somewhat too rigorous and that some of the children might not have required any treatment at all. On the other hand treatment does not entail any real inconvenience and has never had any undesirable effect.

¹ Two years have elapsed since then. At 1 month in plaster the right hip was stable and reduced and the plaster was replaced by a larger model of our frame. This was removed when the child was 3 months old. The child began to walk at 11 months and has run about in a normal way. Roentgenologically the left hip is normal and the right hip has gradually acquired a satisfactory way. On both sides development of the bone nuclei is normal (Fig. 10).

Result of treatment from birth of unstable hips

A 3 year follow up

BY CARL HIRSH & SVEN SCHELLER GÖTEBORG

Introduction

In the early fifties Palmén and Selander pediatricians at different children's hospitals in Sweden started to examine all newborn for dislocation of the hips. Since practically all children in Sweden in 1958 98.9 per cent are delivered in maternity wards a great number of new born were referred to orthopedic departments the first days of life when Ortolani's phenomenon or only unstable hips explained as slack joint capsules had been noticed. Many previous reports had convincingly illustrated that early abduction treatment of congenital hips led to anatomical normalization (Putti 1929, 1933, Irochich 1932, Hilgenreiner 1933, Irejka 1941, Hart 1950). The interest for immediate care grew rapidly throughout this country encouraged by von Rosen (1956), Palmén (1961), Andren (1962). Long term follow ups of closed reduction by the method of Lorenz (1920) have been presented by Wiberg (1939) and Severin (1941) illustrating the inefficiency of this treatment and the number of problems at later age. It is therefore imperative to investigate the development of early treated hips in which at the time of management very few really had a dislocated joint but rather something that was felt indicative of DHI. The purpose of this presentation is to report the present results of the children born in Göteborg in 1961 and 1962.

Material

In Göteborg all children are delivered in two maternity clinics. Each child is examined during the first day of life with regard to hip-joint stability. The frequency of unstable hips in Göteborg was in 1961 for boys 6/3077 (0.2 per cent) and for girls 32/3082 (1.1 per cent). In 1962 the rate was in boys 1/3210 (0.2 per cent) and in girls 19/2971 (1.7 per cent). Arthrogryptic infants were not included.

In these 93 infants 123 hips were unstable. 30 were bilateral and 63 unilateral. 31 in the left and 32 on the right side.

Röntgenograms were taken in all these children. Radiographic indications of congenital hip dysplasia and dislocation were defined with regard to mean and pathologic values at time of birth. 23 hips were considered

was recently placed in Lorenz plaster and I hope and believe that also this hip will become stable and develop normally. The child has hypermobile joints but is of otherwise normal body build.¹

Summing up I believe that this method of treatment devised by us is adequate but one should be on the watch for children with crudd body build and hypermobile joints and also for children with hereditary predisposition. It is possible that our treatment was somewhat too rigorous and that some of the children might not have required any treatment at all. On the other hand treatment does not entail any real inconvenience and has never had any undesirable effect.

Result of treatment from birth of unstable hips

A 5 y a f l l w u p

BY CARL HIRSCH & SVEN SCHELLER GÖTEBORG

Introduction

In the early fifties Palmén and Selander pediatricians at different children's hospitals in Sweden started to examine all newborn for dislocation of the hips. Since practically all children in Sweden in 1958 98.9 per cent are delivered in maternity wards a great number of newborn were referred to orthopaedic departments the first days of life when Ortolani's phenomenon or only unstable hips explained as slack joint capsules had been noticed. Many previous reports had convincingly illustrated that early abduction treatment of congenital hips led to anatomical normalization (Putti 1929, 1933, Froelich 1932, Hildgrenreimer 1935, Frejka 1941, Hart 1950). The interest for immediate care grew rapidly throughout this country encouraged by von Rosen (1956), Palmén (1961), Andren (1962). Long term follow ups of closed reduction by the method of Lorenz (1920) have been presented by Wiberg (1939) and Severin (1941) illustrating the inefficiency of this treatment and the number of problems at later age. It is therefore imperative to investigate the development of early treated hips in which at the time of management very few really had a dislocated joint but rather something that was felt indicative of CDH. The purpose of this presentation is to report the present results of the children born in Göteborg in 1961 and 1962.

Material

In Göteborg all children are delivered in two maternity clinics. Each child is examined during the first day of life with regard to hip-joint stability. The frequency of unstable hips in Göteborg was in 1961 for boys 6/3077 (0.2 per cent) and for girls 32/3062 (1.1 per cent). In 1962 the rate was in boys 6/3210 (0.2 per cent) and in girls 19/2971 (0.7 per cent). Arthrogyposis infants were not included.

In these 93 infants 123 hips were unstable. 30 were bilateral and 63 unilateral. 31 on the left and 32 on the right side.

Roentgenograms were taken in all these children. Radiographic indications of congenital hip dysplasia and dislocation were defined with regard to mean and pathologic values at time of birth. 20 hips were considered

dysplastic or luxated e.g. 20 per cent of the total number of unstable joints. The incidence of radiographically visible changes were in 1961 amongst boys 0.03 per cent and girls 0.1 per cent. In 1962 the figures were 0.06 and 0.3 respectively.

It is hard to tell if those hips which already at birth show evidence of CDH are the only ones to develop a real dislocation if not treated immediately and how many of the radiographically normal hips with clinical signs of instability with or without Ortolani clicks will cause acetabular disturbances and different degrees of joint malformations. It is quite obvious that at least some unstable hips will be normal very soon even if no treatment is given. The degree of instability varies. It is most pronounced the first day of life. Some will be stable if reexamined a few days or a week later. In this study only those were treated where the orthopaedist was able to confirm the findings of the pediatrician both seeing the patient within a day or two.

In order to have some idea of the difference in frequency of dislocations a comparison was made between children born in 1951—55 when early treatment was not completely organized and in 1961—62 when all new born were compulsorily checked. Since the orthopaedic department is the only hospital in Göteborg where the citizens can bring their children if hip involvement is recognized they will turn up sooner or later. Everyone born in 1951—62 regardless of when he or she was admitted for hip disorder was checked. Those with a diagnosis of CDH were recorded. Naturally in this way children with asymptomatic dysplasia or subluxation escaped our efforts. The frequency of congenital dislocations of hips based on radiographic evidence in 1951—55 and in 1961—62 were compared. The incidence was somewhat higher when control at the time of birth was effective.

Even if such a comparison may speak in favour of early roentgenograms in order to find the really severe hips it is obvious that many of the unstable hips will during the radiographic examination be in a normal position. Attempts have been made to take X rays while the femoral head is forced out of its position. In this way some more may be regarded as positive findings but there will still be the majority showing normal roentgenograms. Many of these may nevertheless be potential dislocations. A slack capsule allowing the femoral head abnormal motion in the acetabulum may affect the anatomical shape of the joint (Järngenskiöld & Sirpio 1957, Wilkinson 1963, Stanislavjevic & Mitchell 1963). We therefore decided to treat all children with unstable hips in abduction. In doing so however we did take into consideration the question whether such a joint position might affect the development of the joints whether or not it could harm the epiphyses. Radiograms have been taken at 3 months, one year, two years and at four, five years of age.

Radio graphic normalization of hip dislocation and dysplasia following early abduction treatment

Treatment

Most of the children were splinted in a Lejka type of pillow a few received the aluminum frame of von Rosen or Palmen. The time in abduction varied. In general they were kept 2—4 months. During this period they were checked several times in the out patient department. If the radiograms did indicate dysplasia or luxation they remained in abduction longer. Eventually a plaster of Paris (double hip spica) was made.

Results

At one year of age 89 of the 93 children showed radiographically normal hip-joints. One year later one more child had a normal joint. At age four two children showed very mild dysplasia and in one joint there was only a small difference in the levels of the epiphyseal bone centres in the diagram indicated as dislocation (Fig.). At age five all these children had normal hip-joints.

No radiographic changes have remained in the femoral epiphysis indicating that early abduction is harmful. Delayed development of the epiphyseal bone centre is quite common on the affected side but becomes normal some months later and remains normal.

Summary

The frequency of unstable hips in new-born in Göteborg was in 1961 0·9 per cent for boys and 1·1 per cent for girls in 1962 0·2 and 1·7 per cent respectively. One third was bilateral, one third affected the right and the same proportion the left hip-joint. 20 per cent showed radiographic indications of dysplasia or luxation.

All infants were treated in abduction immediately. With few exceptions a Frejka type of dressing was used in general during two-four months. The children were all checked at intervals radiographically. Within one year 96 per cent (89/93) had completely normal hip-joints. A year later one more child had developed a normal hip. At age four two children still showed evidence of mild dysplasia and one hip was slightly subluxated. At age five these three hips were normal.

As a rule the femoral epiphyseal bone centre developed later on the affected side. No signs of disturbances occurred. After the epiphyseal bone centre had become equal sized it remained normal.

Analysis of a material of congenital dislocation of the hip¹

BY U. JAMES AND J. A. SEVASTIKOGLU, Umeå

The present paper concerns an analysis of a series of congenital dislocations of the hip (CDH) observed in the Department of Orthopaedic Surgery, University Hospital Uppsala in children born during the years 1962 to 1965.

Besides typical cases of congenital dislocation of the hip—preluxation (Palmén 1961)—the series includes some atypical cases such as dislocation combined with other congenital malformations (e.g. arthrogryposis and myelomeningocele).

Material

The patients. As demonstrated in table I altogether 373 children born between 1962 and 1965 were referred to the Department because of diagnosed or suspected CDH.

The material is divided into two groups: newborn, 255 cases referred before 2 weeks of age and infants, 118 cases referred after 2 weeks of age. Of the total number 90 were boys and 283 girls, the ratio for both groups being approximately 1:4.

Table I. The material

	No of newborn referred before 2 weeks of age	No of infants referred after 2 weeks of age	Total	Total boys
Girls	194	89	283	
Boys	61	29	90	373
Delivery in the University Hospital	242	53	295	
Delivery in other hospital	13	65	78	373

¹ Part of the present material has been published by T. Hultén and U. James (1966) pp. 303-312 in *J. Bone Joint Surg.*

The distribution of the patients by the age at which they were referred and first examined in the Orthopaedic Department is shown in table II. More than 88 per cent or 214 of the newborn were examined during the first week of life. 87 per cent or 103 infants were admitted to and examined in the Orthopaedic Department during their first year. 212 newborn and 53 infants were born in the maternity ward of the University Hospital and 13 and 65 respectively in maternity wards of other hospitals in the Uppsala region.

Diagnosis. The hips of all the children born in the University Hospital were examined in the maternity ward by a consultant paediatrician. Children born at other hospitals were examined in the maternity ward either by the surgeon in charge or by a consultant paediatrician. All the children were later examined on several occasions at the children's welfare centres by paediatricians or general practitioners. Every child in whom abnormality of the hips was diagnosed or suspected was immediately transferred to the Department of Orthopaedic Surgery at the University Hospital where a second examination was performed by one of the senior members of the staff.

The diagnosis in the newborn was always based on clinical findings such as Ortolani's click, positive provocation test by Palmén's technique, decreased abduction of the hip, apparent shortening of the leg and suspected crepitations. X-ray examination was performed in the newborn in exceptional cases only.

Treatment and results. Among the total number of children admitted to the Department, 13 newborn and 69 infants were assessed as completely normal and not in need of treatment. The remaining 291 received one of three different types of treatment as shown in table III.

Newborn. The standard treatment was by abduction in a splint, almost exclusively of the Frejka pillow type, usually for three months. No complications were observed in any of the cases thus treated. A small number of newborn altogether 10 babies received special treatment, either with plaster in abduction position or by closed reduction because of persistent dislocation.

Table II. Age and number of children of first examination in the Department of Orthopaedic Surgery, Uppsala.

Age in months	1	2	3	4	5	6	7	8	9	10-14	Total
No. of newborn	6	30	3	53	30	38	25	10	10	8	214
Age in months	1-1	1-3	3-6	6-12	12-14	14					
No. of infants	1	27	40	29	10						118

Only children born in the maternity department of the University Hospital are included.

Among the newborn who received special treatment 7 were born at the University Hospital. Five of them had typical CDH and two atypical CDH (myelomeningocele and arthrogryphosis).

In 1 of these latter cases the reason for special treatment was a slight acetabular dysplasia diagnosed at the regular three month checkings. After a period of prolonged abduction treatment in plaster the hips of these babies developed satisfactorily.

In the other 3 cases (2 typical and 1 atypical) the dislocation persisted in spite of primary treatment by means of a I rejka pillow.

In the first case dislocation of one hip and subluxation of the other were diagnosed on the third day after birth. The baby was treated with a I rejka pillow for 8 weeks but dislocation persisted. Closed reduction was therefore performed and a plaster cast was applied for a further 8 months. The development was then very satisfactory. In the second case laxity of one hip with Ortolani's click was diagnosed on the fifth day after birth. The baby was placed in a I rejka pillow for 2 months. The X-ray examination 5 months later showed however dysplasia of the acetabulum with subluxation of the femoral head. Closed reduction was therefore performed and a plaster cast was applied for 7 months. The development of the hip was then very satisfactory. The third case (the atypical one) occurred in a baby with arthrogryphosis in whom dislocation of both hips was diagnosed the fifth day after birth. Traction of the hips was applied for some days and closed reduction was then attempted but the result was not satisfactory. After open reduction of both hips and prolonged immobilization in plaster a very satisfactory result was obtained.

Infants. Out of the 118 infants between 2 weeks and 2 years old referred to the Department of Orthopaedic Surgery because of diagnosed or suspected hip abnormalities only 19 received any form of treatment. 23 of these children were born in the University Hospital and had therefore been examined immediately after birth in the maternity department. In 18 out of these 23 cases treatment was considered indicated because of slight ac-

Infants				17 ()	19

labular dysplasia, small capital epiphyses or limitation of abduction but no established dislocation. As far as we know, the hips later developed normally in all these 18 children.

The remaining 5 cases (4 typical and 1 atypical) occurred in children with established dislocation who received special treatment

In three of them dislocation of one hip was diagnosed between 3½ and 4 months after birth. Closed reduction and immobilization in plaster gave very satisfactory results in all 3 cases. In another child dislocation of one hip was diagnosed at the age of 1 year. The child had been treated earlier for congenital megacolon but no other congenital abnormalities had been found. The dislocated hip was treated by closed reduction and immobilization in plaster also with a satisfactory result.

The fifth case (the atypical one) was that of the child with multiple congenital anomalies such as anal atresia, urinary tract malformations and deformity of the sacrum. Dislocation of one hip was diagnosed soon after birth, in about the 4th week of life, and was treated first by immobilization in plaster and later, because of a pronounced dysplasia of the acetabulum and valgus deformity of the hip, by open reduction combined with a varisation osteotomy.

Discussion

The present material is composed of a) children born in the maternity department of the University Hospital, 293 cases, and b) children born in maternity departments of other hospitals in the Uppsala region, 78 cases. All the children belonging to the first group were examined for abnormalities of the hip joints by a consultant paediatrician, as a rule on the first and seldom later than the third day after birth. The material of group a is therefore considered to be more homogeneous and reliable than that of group b and will be analyzed separately below.

Altogether 11 868 children were delivered in the University Hospital during the four year period 1962–1965. In 242 newborn the consultant paediatrician found positive or suspected signs of CDH by the primary examination. These babies were referred to the Orthopaedic Department. The incidence of referred cases thus amounted to as much as approximately 2 % of all the births (table IV). Earlier analyses of similar Swedish materials have provided data suggesting a lower incidence of these abnormalities. Thus among 12 394 examined newborn a total incidence of positive Ortolani's click or subluxation provocation of 2.7 % has been reported (Palmén 1961) while among 11 375 examined newborn genuine dislocation was diagnosed in 2.1 % and doubtful dislocation in another 1.2 % making a total of 3.6 % (Fimneus 1966).

Among the newborn who received special treatment 7 were born at the University Hospital. Five of them had typical CDH and two atypical CDH (myelomeningocele and arthrogryphosis).

In 4 of these latter cases the reason for special treatment was a slight acetabular dysplasia diagnosed at the regular three month checkings. After a period of prolonged abduction treatment in plaster the hips of these babies developed satisfactorily.

In the other 3 cases (2 typical and 1 atypical) the dislocation persisted in spite of primary treatment by means of a Frejka pillow.

In the first case dislocation of one hip and subluxation of the other were diagnosed on the third day after birth. The baby was treated with a Frejka pillow for 8 weeks but dislocation persisted. Closed reduction was therefore performed and a plaster cast was applied for a further 8 months. The development was then very satisfactory. In the second case laxity of one hip with Ortolani's click was diagnosed on the fifth day after birth. The baby was placed in a Frejka pillow for 2 months. The X ray examination 5 months later showed however dysplasia of the acetabulum with subluxation of the femoral head. Closed reduction was therefore performed and a plaster cast was applied for 7 months. The development of the hip was then very satisfactory. The third case (the atypical one) occurred in a baby with arthrogryphosis in whom dislocation of both hips was diagnosed the fifth day after birth. Traction of the hips was applied for some days and closed reduction was then attempted but the result was not satisfactory. After open reduction of both hips and prolonged immobilization in plaster a very satisfactory result was obtained.

Infants. Out of the 118 infants between 2 weeks and 2 years old referred to the Department of Orthopaedic Surgery because of diagnosed or suspected hip abnormalities only 19 received any form of treatment. 23 of these children were born in the University Hospital and had therefore been examined immediately after birth in the maternity department. In 18 out of these 23 cases treatment was considered indicated because of slight ace-

tabular dysplasia small capital epiphyses or limitation of abduction but no established dislocation. As far as we know the hips later developed normally in all these 18 children.

The remaining 3 cases (4 typical and 1 atypical) occurred in children with established dislocation who received special treatment

In three of them dislocation of one hip was diagnosed between 3 $\frac{1}{2}$ and 4 months after birth. Closed reduction and immobilization in plaster gave very satisfactory results in all 3 cases. In another child dislocation of one hip was diagnosed at the age of 1 year. The child had been treated earlier for congenital megacolon but no other congenital abnormalities had been found. The dislocated hip was treated by closed reduction and immobilization in plaster also with a satisfactory result.

The fifth case (the atypical one) was that of the child with multiple congenital anomalies such as anal atresia urinary tract malformations and deformity of the sacrum. Dislocation of one hip was diagnosed soon after birth in about the 4th week of life and was treated first by immobilization in plaster and later because of a pronounced dysplasia of the acetabulum and valgus deformity of the hip by open reduction combined with a varisation osteotomy.

Discussion

The present material is composed of a) children born in the maternity department of the University Hospital 293 cases and b) children born in maternity departments of other hospitals in the Uppsala region 78 cases. All the children belonging to the first group were examined for abnormalities of the hip joints by a consultant pediatrician as a rule on the first and seldom later than the third day after birth. The material of group a is therefore considered to be more homogeneous and reliable than that of group b and will be analyzed separately below.

Altogether 11 868 children were delivered in the University Hospital during the four year period 1962—1965. In 212 newborn the consultant pediatrician found positive or suspected signs of CDH by the primary examination. These babies were referred to the Orthopaedic Department. The incidence of referred cases thus amounted to as much as approximately 2 % of all the births (table IV). Earlier analyses of similar Swedish materials have provided data suggesting a lower incidence of these abnormalities. Thus among 12 394 examined newborn a total incidence of positive Ortolani's click or subluxation provocation of 2.7 % has been reported (Palmén 1961) while among 11 373 examined newborn genuine dislocation was diagnosed in 2.1 % and doubtful dislocation in another 1.2 % making a total of 3.6 % (Linnäs 1966).

The strikingly higher incidence observed in the present material is undoubtedly attributable to overdiagnosis of these abnormalities in the Uppsala series. The primarily suspected or established diagnosis was verified at the second examination in the Orthopaedic Department in only about 57 % of the admitted, but the incidence is still almost 2 to 3 times as high as that reported earlier. The newborn babies who did not get any form of treatment comprised 5 % although the primary diagnosis could be verified in only 57 % of the total number of newborn. This means that about 10 % of the newborn underwent the standard treatment in spite of the fact that no signs of hip abnormality could be verified at the orthopaedic examination. The reason for this overtreatment was usually that one or more days elapsed between the two examinations and that the indication for treatment was based on the findings of the primary rather than on those of the second examination.

In 5 cases (including 1 atypical case) or 0.42 % of all the births an established dislocation diagnosed later was not detected in the maternity department at the primary examination which thus failed.

The dislocation was detected in all cases but one however before 11 months of age. The primary examiner in the maternity department has a key role and he is responsible if laxity is overdiagnosed or missed. Repeated examinations in the newborn period seem to be important.

The fact that 3 cases (including 1 atypical) or 0.25 % of the total number of births showed persistent dislocation in spite of early treatment with a 1 reka pillow indicates that this treatment is not always sufficient. Much better results with the use of the other types of splints have been reported (von

Instability of the hip in new born infants

1958 1960

81 children 114 hips

Fig. 1 Distribution by sex and inst.

The physical position is applied on the internal side of the thigh on the anterior surface of the femur. The long end of the fac. interne et sa pulpe appuie sur la région trochantérienne. L'annulaire et le petit doigt pèsent l'os iliaque. La cuisse est maintenue fléchie. L'angle droit sur le bassin la jambe est également fléchie et on le tient sur la cuisse. L'opérateur utilise volontiers l'un de membres inférieurs pour immobiliser l'autre. Il n'est pas nécessaire d'examiner l'autre. Dans un premier temps la cuisse est fixée comme il est dit. L'opérateur attend que la pulpe du pouce propulse le fémur de la cuisse et pendant que la commissure du pouce appuie sur le genou. Si la tige est subluxable on sent parfois un secousse due à la subluxation de la tête fémorale. Dans un deuxième temps l'opérateur imprime à la cuisse un déplacement vers le haut. La pulpe du médius pousse le trochanter d'arrière en avant et le fémur se déplace pendant que la cuisse est maintenue en abduction. Par cette manœuvre il est visible la tête rentre dans la cavité cotyloïdée par dessus le bord postérieur et se trouve à l'arrière. Les jours d'un test sont assez légers souvent forte nettement arrive à l'arrière et assez bruyant pour qu'on l'entende.

The clinical examination in our cases was made

partly as simple abduction or adduction without exerting any pressure at all on the thigh in any direction

partly by using the technique described by Le Damany for provocation of the resart

We observed three degrees of instability which were not sharply defined and the following clinical grouping was obtained

Instability of the hip in the newborn

Classification for elective treatment pathogenesis of the dislocation and complication

BY M. FELLANDER, H. GLADNIKOFF & F. JACOBSON

Since 1958 examination of the hips in newborn infants by Ortolani's method has been a routine procedure in the maternity units in the Stockholm area. Ortolani's *segno dello scatto* (signe de ressaut) signifies essentially that there is a ridge over which the femoral head is felt to glide. A click is an unfortunate error in translation of *segno dello scatto*. Clicks of unknown nature can often be felt on palpation at Ortolani's manoeuvre but unlike gliding they are harmless phenomena which have no relation to Ortolani's sign. We prefer the term 'ridge phenomenon'.

Own material

In the Stockholm area virtually all the infants with suspected hip dislocation have been transferred to the Children's Hospital Samariten for further investigation and treatment. Over the period 1958-1960 we found 114 hips with gliding over a ridge in 81 newborn examined clinically and radiographically at 1 to 4 days of age. The distribution by sex and involved side will be seen in Fig. 1. They were followed clinically and radiographically up to the age of 5 to 7 years with the exception of 11 children who were observed only up to the age of 2 to 4 years and could not be traced for follow up examination.

Clinical examination

Clinical examination is in the main carried out in the same way as that originally described by Le Dumas and commendably revived by Ortolani (and by Palmén in Sweden). In its classical simplicity Le Dumas's description of this 'ressaut' deserves to be quoted here:

L'enfant est couché sur le dos sur une table d'opérateur placée en face de lui. Avec douceur sans aucune force, il saisit chacune des jambes du nouveau-né avec l'un ou l'autre index opposé de telle sorte que la commissure de son pouce embrasse le genou de l'enfant.

Instability of the hip in new born infants

1958 1960

81 children 114 hips

Fig. 1. Distribution by age, sex, and site.

La pulpe du pouce est appliquée sur la face interne de la cuisse. L'index sur la face antérieure du médus s'étend le long de sa face externe et sa pulpe appuie sur la région trochantérienne. L'annulaire et le petit doigt repliés entourent le mollet. La cuisse est ainsi maintenue fléchie à l'endroit où l'assise la jambe est également fléchie à l'endroit droit sur l'axe. L'opérateur utilise volontiers l'un de ses membres inférieurs pour immobiliser l'un pendant qu'il examine l'autre. Dans un premier temps la cuisse fixée comme il est dit est portée en adduction pendant que la pulpe du pouce propul légèrement de dedans vers l'extérieur de cette cuisse et pendant que la commissure du pouce agit sur le genou. Si la hanche est subluxable on sent parfois une secousse due à la fixation de la tête fémorale. Dans un deuxième temps l'opérateur imprime à la cuisse un déplacement vers l'arrière. La pulpe du médus pousse le trochanter d'arrière en avant et le doigt index dans l'angle que la cuisse est portée en abduction. Par cette manœuvre il est possible de faire rentrer la tête fémorale dans la cavité coxo-fémorale par dessus le bord postérieur et de sentir sa mise en place toujours d'un seul saut. Parfois si l'effort est souvent fort net il arrive qu'il y ait un saut assez bruyant pour qu'on l'entende.

The clinical examination in our cases was made

partly as simple abduction or adduction without exerting any pressure at all on the thigh in any direction

partly by using the technique described by Le Damany for provocation of this resaut

We observed three degrees of instability which were not sharply defined and the following clinical grouping was obtained

Instability of the hip in the newborn

Classification for selective treatment pathogene is of the dislocation and complications

BY M. FELLANDER, H. GLADNIKOFF & E. JACOBSON

Since 1958 examination of the hips in newborn infants by Ortolani's method has been a routine procedure in the maternity units in the Stockholm area. Ortolani's *segno dello scatto* (*signe de ressaut*) signifies essentially that there is a ridge over which the femoral head is felt to glide. A click is an unfortunate error in translation of *segno dello scatto*. Clicks of unknown nature can often be felt on palpation at Ortolani's manoeuvre but unlike gliding they are harmless phenomena which have no relation to Ortolani's sign. We prefer the term ridge phenomenon.

Own material

In the Stockholm area virtually all the infants with suspected hip dislocation have been transferred to the Children's Hospital Samariten for further investigation and treatment. Over the period 1958–1960 we found 114 hips with gliding over a ridge in 81 newborn examined clinically and radiographically at 1 to 4 days of age. The distribution by sex and involved side will be seen in Fig. 1. They were followed clinically and radiographically up to the age of 5 to 7 years with the exception of 11 children who were observed only up to the age of 2 to 4 years and could not be traced for follow up examination.

Clinical examination

Clinical examination is in the main carried out in the same way as that originally described by Le Damany and commendably revived by Ortolani (and by Palmén in Sweden). In its classical simplicity Le Damany's description of this *ressaut* deserves to be quoted here:

L'enfant est couché sur le dos sur une table. L'opérateur se place en face de lui. Avec douceur sans aucune force il saisit chacune des jambes du nouveau né avec la main de son opposé de telle sorte que la commissure de son pouce emboîte le genou de l'enfant.

From the Children's Hospital Samariten and the Orthopaedic Department, St. Erik's Hospital, Stockholm.

and ischium are projected in the same transversal plane. The thighs should be extended in the hip joints and rotated inwards so that the lesser trochanters are barely visible (Fig. 2). The ossification zones of the acetabular roofs will be clearly visible and on subsequent films in the same view even small deviations from the rapid neonatal ossification process will be seen.

Anatomy of the hip in the newborn. Two thirds of the acetabular roof are chondral (Fig. 3). The osseous surface of the roof appears plane and steeply sloping and is very short (Fig. 2). The bone usually ends laterally in a margin at the transition into cartilage. This margin is very small or absent at late ossification. This is not dysplasia but an *ossification anomaly*.

A periacetabular recess on the outer side of the edge of the labrum is visible in anatomic specimens (Fig. 3). At *arthography* the contrast in this recess (Fig. 4 b) indicates the position of the edge. The adjoining half of the acetabular roof is still chondral. The *articular surface* of the roof consists of a single caudally directed concavity. Consequently the plane steeply sloping short osseous surface of the roof is *unusable in the assessment of the articular surface*. The pressure from the femoral head is distributed over the entire acetabulum.

The *morbid anatomy* is visible in arthrograms (Figs. 4 a, 5, 6 and 7). The medial part of the acetabulum is empty before the femoral head is felt to pass over the ridge (Fig. 4 a) which means that it is not in contact with the joint head. The pressure from the femoral head is still concentrated wholly on the lateral part of the roof which is still chondral and has kinked it cranially. As a result the concavity of the acetabular roof is divided into a medial osseous part and a lateral chondral part. An intersection between

Fig. 2 Standard X-ray of pelvis of a newborn. The cranial borders of the pubis and ischium in the same transversal plane. The ossification zone of the acetabular roof is clearly visible.

- 1 *Instability without dislocation*—the joint head is in normal and constant position in the acetabulum but can be dislocated dorsally (subluxation provocation)
- 2 *Instability with inconstant dislocation*
- 3 *Constant dislocation*

We based the indications for treatment on these degrees of instability

Instability without dislocation disappears within 1 to 7 days (occasionally longer time) treatment is not necessary

Instability with inconstant dislocation implies that a ridge or gliding phenomenon (signe de ressaut) is felt once or several times at repeated examinations. Spontaneous correction and stabilisation can also occur within 1 or 2 weeks in these cases. All cases will not heal spontaneously however. It takes an experienced examiner to decide whether to treat such a hip promptly or to await possible spontaneous regression. We have some times used expectant treatment for up to 2 weeks before making the final decision. In each case this decision was then based on the X-ray examination together with the tendency to spontaneous healing.

Constant dislocation is treated promptly by immobilisation in an abduction splint.

The group that was thus left untreated but was under careful observation comprised 39 children with 45 affected hips (Table I). The remaining 42 children with 69 affected hips were treated in a von Rosen splint for 2 to 4 months. Most of them were kept in the hospital for a short time so that the mothers could learn to nurse them in their splints. The splints were removed at bathing or changing of nappies care being taken to assure that the child's legs remained in the abducted position.

X ray examination

The initial X ray examination of the newborn requires only one straight anteroposterior view of the pelvis in which the cranial borders of the pubis

Table I. *Instability of the hip in newborn 1955-1960*

Examination technique	Treatment	No. of children	No. of hips
Ortolani's abduction manoeuvre	Abduction splint 2-4 months	42	69
Subluxation provocation	None	39	45
Total		81	114

Fig. 4 The ridge phenomenon

- a) The dislocated head has no contact with the medial part of the acetabulum. Its pressure kinks the chondral part of the roof cranially and as a result the roof is divided into a medial and a lateral concavity. The intersection between the two concavities forms a ridge (1). The periacetabular recess (2) indicates the edge (3) of the labrum.
- b) At the direction of the tabulum is one concavity up to the edge of the labrum (3). It protrudes distally over the entire acetabulum. The kink and the ridge are identical.

with the head outside the acetabulum and with the labrum infolded by the dislocated head could not be demonstrated in any of the cases.

Secondary changes may arise at three sites around the line between the bony margin in the acetabular roof and the lesser trochanter namely 1) in the osseous margin of the roof 2) in the head and 3) in the neck usually they are combined (Fig. 6). The initial appearance of the changes as well

Fig 3 Specimen of hip in a newborn. Only the dark area in the centre of the acetabulum is ossified—about one third of its surface. The light periphery is entirely chondral and comprises two thirds of its surface. The joint capsule is attached to the outer side of the acetabulum 2–3 mm from the rim, with resulting formation of a periacetabular recess all round the outer side (the recess is indicated by arrows).

the two concavities must form a ridge—this ridge is visible where the femoral head loses its contact with the acetabulum.

Abduction brings about a reduction. The hump, the lateral concavity and the ridge are eliminated at the reduction. They reappear after the corresponding dislocation manoeuvre. Consequently the ridge visualised by arthrography in our children corresponds to the ridge that can be felt during the performance of Ortolani's abduction manoeuvre. These reversible changes cannot be expected always to remain visible when the joint is opened and the head removed for inspection of the roof, because the pressure of the head is then eliminated.

Both cranial kinking of the acetabular roof and the ridge phenomenon were present in all the 9 children who were examined at an early stage by arthrography. In 2 of them the ridge bilaterally was more distinct (Fig 5); the two concavities here intersect each other at almost right angles. In variation

Such changes in the femoral head were noted in 43 hips of 23 children (Table II). Over bridging of the ossification defects in the head begins at about 1 year of age. The bony structure and the shape become slowly normal up to the age of 5 to 8 years. Flattening of the head and incongruence with the acetabulum may persist, however, especially if bone changes have also been present in the neck.

Changes in the neck of the femur are often visible initially as small ossification defects shaped like an axe cut or as a step like progressive break (Fig. 6) in the bone close to the epiphyseal cartilage and may appear before or after the ossification of the head. When the ossification of the head begins the axe cut in the neck often proves to be a continuation distal to the epiphyseal cartilage of a lamellar ossification defect through the head and like this it is frontal or sagittal.

The axe cut or break may grow deeper and wider to become cup shaped; this weakens the neck and may result in ante- or retroversion of the head and in varus deformity of the neck (Fig. 7g). Bulbiform rarefaction, hypermineralised clumps as well as bone absorption are often present as in the head.

Femoral neck changes occurred in 32 hips of 21 children and were in every case associated with lesions of the head.

The bony changes in the neck disappear partially or entirely before the age of 5 to 8 years except for any varus deformity which may persist.

Distinct but slight femoral head changes developed in 4 hips of 4 out of the 39 children who were left untreated because the instability was not attended with constant dislocation and became quickly corrected. In these 4 hips the bone changes disappeared completely. Dislocation with abnormal pressure could have been present prenatally and caused the changes. Too ungently or repeated examinations are another possible cause that cannot be excluded.

Bone changes also developed in 4 hips without demonstrable instability in 11 children with instability of one hip for which they were treated by immobilisation in a position of abduction. These bone changes disappeared only partly but in no case did they cause any apparent functional disturbance apart from some limitation of abduction.

Follow up examinations and results

70 of the 81 children were re-examined at the age of 5 to 7 years. As regards the other 11 the results were assessed from the last examination at the age of 2 to 4 years. Clinical and radiographic results will be reported separately in the following.

as their connection with the dynamics of the dislocation and with one another are of interest

Ossification defects in the acetabular roof are seldom visible as early as the first days of life (Fig 6 a) they usually develop at the age of 1 to 3 months in bone tissue that is normal at birth (Fig 7) They may appear shallow or cup shaped or more well marked at the site of the bony margin of the roof and are often associated with retardation of the normal decrease in the inclination of the bony roof during the neonatal period This dysplasia hypoplasia or false acetabula gradually increases or remains until reduction takes place

Such ossification defects in the acetabular roof were found in 33 hips of 21 children (Table II) In 1 children such defects also developed on the side on which no gliding over a ridge was noted The defects in the healthy hips were probably residual changes after dislocation which had healed after spontaneous reduction and stabilisation of the joint prenatally

Changes in the head of the femur are more common than in the acetabulum and in the neck The ossification of the head is retarded and proceeds slowly The bone nucleus may be wholly (Fig 7) or partially (Fig 6) divided into two parts by a frontal or sagittal ossification defect either shaped like the

Fig. 1. Pronounced bone changes in the roof, head and neck.

- a) 1 day. Minimal ossification defects (✓ and ∨) in the acetabular roofs.
- b) 7 weeks. The ossification defects have increased in size and the inclination of the bony roofs has not decreased.
- c) 10 weeks. Extension. The dislocated joint head presses the lateral part of the acetabular roof cranially. The pressure is transmitted to the bone defect (✓).
- d) 10 weeks. 90° abduction. At reduction the pressure of the head on the roof and the bone defect is eliminated.
- e) 10 months. (After treatment in an abduction splint for 2 months.) Only small remnants of the bone defects. The inclination of the bony roofs has become normal. A frontal cut-shaped ossification defect is seen in the right joint head (✓) extending in the shape of an axe-cut into the neck close to the epiphyseal cartilage (β). The ventral border of the femoral neck is pressed distally (γ).
- f) 12 months. Progress.
- g) 4 years. Persistent dysplasia of the left acetabulum and deformity of the left joint head with fragmentation of the bone nucleus. Slight changes in shape and structure of the right head and neck. Varus deformity bilaterally.

Clinical results In 1 child with a bilateral ridge phenomenon dislocation of one hip could not be reduced either by splintage or by other closed orthopaedic measures. Open reduction was performed at the age of 1 $\frac{1}{2}$ years. As regards the other 113 hips reduction was achieved by treatment in a splint and resulted in permanent stability. At the follow-up examination all the children were subjectively free from symptoms. Objectively Trendelenburg's test was negative and walking ability normal in all the cases, but a slight limitation of abduction was noted in 10 cases.

Radiographic results An ossification defect in the acetabular roof was still present at the follow up examination in 8 hips of 6 children (Table III). In one of them who had dislocation of one hip joint extensive changes were also present in the femoral head and neck with varus deformity. In the remaining 7 hips the examination showed only slight dysplasia of the acetabular roof without any other radiographic abnormalities.

Changes in the femoral head possible also in the neck were noted in 10 hips (Table III). They were designated as slight in 19, moderate in 8 and severe in 13 hips. The latter group was characterised by marked deformity of both the head and the neck. Varus deformity of varying degree was noted in 11 hips of 9 children, in 2 of them so severe that corrective osteotomy was performed.

Discussion

With respect to *treatment* our series of cases differs from other series reported at this symposium in that we left some clear-cut cases untreated. This policy had no ill effects in the form of persistent dislocation or dysplasia of the acetabulum.

Many workers use immobilisation in the abducted position for every unstable hip, irrespectively of the character of the instability. Immobilisation in the abducted position will not do any harm. Long term immobilisation however can be followed by more or less marked bone changes in the head and neck of the femur, possibly as a result of nutritional disturbances in an abnormally fixed position.

As regards the *X ray diagnosis* Caffey 1950 states: Roentgen diagnosis during the neonatal period and first months of life is exceedingly difficult and often congenital dislocation can be neither identified nor excluded satisfactorily on the basis of roentgen findings. Andren and von Rosen in 1958 published a new projection with inward rotation and 15° abduction of the legs. It was claimed to demonstrate hip dislocation with certainty in the newborn. A line through the long axis of the femoral shaft should pass through or cranially to the lateral edge of the roof. But as will be seen from Figs. 1 and 8 this new projection can be misleading and like the old one it

- a Limitation of Flexion and Extension
 b Limitation of Abduction and Adduction
 c Limitation of Internal Rotation
 d Limitation of External Rotation
 e Limitation of Flexion and Extension
1. Limitation of Flexion and Extension: present if the extension of the femur is limited by the position of the acetabular roof when the femur is in a position of flexion and extension.
2. Limitation of Abduction and Adduction: present if the head can be moved laterally and medially by the change in internal rotation or abduction.
3. Limitation of Internal Rotation: present if the head can be moved medially by the change in internal rotation or abduction.
4. Limitation of External Rotation: present if the head can be moved laterally by the change in internal rotation or abduction.
5. Limitation of Flexion and Extension: present if the head can be moved anteriorly and posteriorly by the change in internal rotation or abduction.

can often neither identify nor exclude dislocation. It can be misleading because 1) the joint head can be temporarily reduced at this projection 2) the projection will not always be exact and 3) the position of the *bony margin of the acetabular roof* varies at varying degree of ossification and is not identical with the *acetabular margin*. The latter is chondral neonatally and situated about 1 cm lateral to the bony margin.

In the early part of our work with neonatal hips we used arthrography as a means of studying the pathological anatomy and in particular the nature of the ridge in the hope of obtaining further insight into the nature of the disease and guidance in the treatment. But arthrography is too complicated as a routine method and not entirely free from risks. X-ray examination 1 1/2 to 3 months later, on the other hand, will show any deviations from the normal ossification of the acetabular roofs that is the condition can be assessed at a time when the clinical findings including the ridge phenomenon are not certain. A comparison with films of the hips during the neonatal period will make the assessment easier.

Our arthrographies have shown that the ridge phenomenon is due to cranial kinking of the labrum with resulting formation of a ridge. A well marked ridge of this type (Fig 5) observed in 2 cases was earlier interpreted by orthopaedic surgeons and radiologists (Severin Caffey, and others) as a labrum that is infolded by a luxated femoral head. The following two details indicate that this is not the case. 1) The periacetabular recess demonstrates the edge of the labrum at a point about 1 cm cranio-lateral from the ridge hence the edge is not infolded. 2) A 15-degree abduction of the femur shifts the pressure of the femoral head medially towards the ridge which will then assume the same flat shape and size as in the other 7 arthrography cases (Fig 5). The cartilagenous part of the acetabular roof in these 2 children seems to be unusually soft the well marked ridge is otherwise of the same kind as the flat ridge in the others. *Accordingly in all hips of 9 newborn infants examined by arthrography the dislocation was a subluxation caused by insufficient firmness of the chondral part of the roof.* This insufficiency explains the instability of the head in the acetabulum.

Reports on newborn infants with the head of the femur wholly outside the acetabulum as in older children with inveterate dislocation have been published by other investigators but their cases would appear to be exceptions or to have been incorrectly interpreted.

Secondary changes. The changes in the roof should not be mistaken for the normal variation already mentioned and seen in late ossification namely bilateral absence of ossification of the acetabular roof or very small osseous margins with unusually steep but symmetric inclination of the bony roof. The remaining ossified part of the acetabulum appears extremely shallow. This is not dysplasia as Putti believed for the bony margin appears a few

weeks later and the acetabulum including its chondral roof has normal shape and depth increases and the inclination decreases as ossification proceeds. The chondral acetabular roof is usually normal in firmness and function.

The defects may be produced by the pressure from the dislocated femoral head. The entire pressure is concentrated to the cranially kinked chondral part of the roof (Figs 5, 6 and 7) and in this pre osseous cartilage the ossification ceases. If unilateral the damage results in asymmetry of the hips. The defect demonstrates that there is or has been a dislocation.

Our pressure damage theory is supported by the fact that reduction which eliminates this abnormal pressure is followed by normalisation. This begins with ossification from the bottom of the defect and at the same time the inclination of the bony roof decreases, its length increases and it becomes normal or subnormal with slightly concave surface. The normalisation of the roof is usually completed when the ossification of the head begins. As a rule normal conditions of the roof are completely re-instated within the first year of life but in 8 hips the bony roof remained tilted cranially and became rough and sclerotic. It may then be difficult or impossible radiologically and without arthrography to determine at once whether this residual change is due to failure of reduction or merely to slow normalisation.

Changes in the head and neck of the femur are much more common in our cases than in other published series. One—and the main—explanation of this would probably be that more or less uncertain cases with inconstant clicks etc. were not included in our series which meant a more concentrated and selected primary material. Another reason could of course be that very slight radiographic late changes were also recorded in our cases. The fact remains however that the changes were pronounced in 11% of the total number of cases and varus deformity was so severe in 2 cases that corrective osteotomy had to be performed. The possibility cannot be excluded that too rigid immobilisation in the splint could (via nutritional disturbances) have given rise to these changes in the head and neck of the femur.

Summary

The series comprises 111 hips in 81 newborn infants with Ortolani's ridge phenomenon from the period 1958–1960.

The nature of the ridge phenomenon was demonstrated by arthrography. The pressure from the joint head kinks the chondral part of the acetabular roof cranially with the result that a ridge is formed at the transition into the osseous part of the roof.

Bone changes in the acetabular roof were present in 33 hips and were still noted at the follow up examination in 7% of the cases.

can often neither identify nor exclude dislocation. It can be misleading because 1) the joint head can be temporarily reduced at this projection 2) the projection will not always be exact and 3) the position of the *bony margin of the acetabular roof* varies at varying degree of ossification and is *not identical with the acetabular margin*. The latter is chondral neonatally and situated about 1 cm lateral to the bony margin.

In the early part of our work with neonatal hips we used arthrography as a means of studying the pathological anatomy and in particular the nature of the ridge in the hope of obtaining further insight into the nature of the disease and guidance in the treatment. But arthrography is too complicated as a routine method and not entirely free from risks. X-ray examination 1 1/2 to 3 months later on the other hand will show any deviations from the normal ossification of the acetabular roofs that is the condition can be assessed at a time when the clinical findings including the ridge phenomenon are not certain. A comparison with films of the hips during the neonatal period will make the assessment easier.

Our arthrographies have shown that the ridge phenomenon is due to cranial kinking of the labrum with resulting formation of a ridge. A well marked ridge of this type (Fig. 5) observed in 2 cases was earlier interpreted by orthopaedic surgeons and radiologists (Severin, Caffey and others) as a labrum that is infolded by a luxated femoral head. The following two details indicate that this is not the case. 1) The periacetabular recess demonstrates the edge of the labrum at a point about 1 cm cranio-lateral from the ridge hence the edge is not infolded. 2) A 15-degree abduction of the femur shifts the pressure of the femoral head medially towards the ridge which will then assume the same flat shape and size as in the other 7 arthrography cases (Fig. 5). The cartilagenous part of the acetabular roof in these 2 children seems to be unusually soft the well marked ridge is otherwise of the same kind as the flat ridge in the others. Accordingly in all hips of 9 newborn infants examined by arthrography the dislocation was a subluxation caused by insufficient firmness of the chondral part of the roof. This insufficiency explains the instability of the head in the acetabulum.

Reports on newborn infants with the head of the femur wholly outside the acetabulum as in older children with inveterate dislocation have been published by other investigators but their cases would appear to be exceptions or to have been incorrectly interpreted.

Secondary changes. The changes in the roof should not be mistaken for the normal variation already mentioned and seen in late ossification namely bilateral absence of ossification of the acetabular roof or very small osseous margins with unusually steep but symmetric inclination of the bony roof. The remaining ossified part of the acetabulum appears extremely shallow. This is not dysplasia as Putti believed for the bony margin appears a few

Brief contributions to the subject

NILS LINDSTROM HARNOSAND

My contribution to the discussion on the unstable hips will be a short account of our experiences in the Orthopaedic Clinic at Harnosand. Owing to the situation of our clinic at a fair distance from each of the county's general hospitals we were rather late in starting to receive fresh cases. Between 1958 and 1959 only 1 fresh case in a newborn infant was referred to us and in each of the years 1960 and 1962 we received 2 cases. During the same period of time the following numbers of missed cases were treated in the clinic: 12 cases in 1958, 5 cases in 1959, 2 cases in 1960 and 1 case in 1961. This means that in the first period 1958 to 1961 we treated only 6 newborn infants with unstable hips while at the same time we had 20 missed cases. I have now looked through the records from this period and found that the latter group included babies who had earlier been treated on a frame which had been removed at bathing or changing of nappies. In consultation with the paediatricians in the county it was agreed upon that from then on we should primarily have the care of all infants with suspected hip dislocation.

In the following five year period we received and treated 15 newborn babies in 1962, 10 in 1963, 22 in 1965, 33 in 1964 and 16 in 1966, all being cases of unstable hips. But each year we still received on an average 1 case which had been missed at birth. So over the period 1962—1966 we treated 96 infants with unstable hips who were referred to us before they were one week old or in some cases at the age of eight days. Over the same period of time we received 6 missed cases. It is probably to be expected that a few cases will always be missed at the routine examination after birth, all the more so as all the hospitals in the county except two lack paediatric service.

We have placed every newborn infant with an unstable hip in a von Rosen splint which was not removed at changing of nappies or at bathing. The splint was left on for three months. I have not been able to find any case of redislocation among the 102 fresh cases thus treated over the period covered by the study 1958—1966.

But on looking through the records I noted a detail that seemed worth

Ossification defects of the head and neck of the femur were present in 13 hips and at follow-up examination found to persist to a marked degree in 11 % of the total number of cases

Clinical manifestations of these bone changes are usually absent but 2 of our patients had a varus deformity of such a degree that corrective osteotomy was necessary

Fig. 1 Girl born 16/5 1961. Reduction under anaesthesia 1/3 1961. Immobilized in plaster for 3 months. X-ray picture taken at the age of 1½ years.

Fig. 2 The same girl as Fig. 1 at the age of 2½ years. Note the osteochondroma.

Osteochondrosis of capitulum epiphysis has been up for discussion. The Lund series from 1961–1961 included no cases that could be so designated. But I can show one case from the Orthopaedic Department at Uddvall.

(see report) A girl born in May 1961, dislocation was not detected until she was three months old. She was then examined under anaesthesia and immobilized in plaster for three months. When she was six months old the nucleus of the dislocated hip was very small. A change in the epiphysis can be seen but at this stage the appearance does not resemble that of osteochondrosis. At the age of 1–2 years there is distinct fragmentation of the epiphyseal nucleus (see Figs 1 and 2). This is of course a case of late treatment of more classical type and not of treatment in the newborn period.

reconsidering I discovered that there were several infants who had not been brought back to us for routine checkings after the splint had been removed at the age of three months. Some infants may of course have died or been taken elsewhere for re-examination. Although none has been referred to us again with redislocation it is not satisfactory, as we should have liked to follow them up to the age of three years.

Therefore I have in mind to start a card index system like that used in the tumour centre at the Radiumhemmet so that children who do not return as arranged can be called to appear for re-examination. I should like to know your experiences and your opinion as regards this detail of the follow-up of newborn babies with unstable hips.

HANS EMNEUS UDDEVALLA

I have not had time for a complete re-examination of the records of my old Lund series dating back to the period 1961—1964. I have been able to confirm however that one case was missed in the Maternity Department at Lund in 1964. The case was diagnosed as typical classical dislocation in the autumn of 1965 in the Orthopaedic Clinic at Lund. No other cases were missed over the period 1961—1964.

As was mentioned in my paper of 1966 some of the children had by then been observed for just under one year. During the past year however there have been no developments suggesting that the infants born in 1964 would show complications other than those seen in the years 1961—1963. But as I have no new actual figures I will make some comments in quite general terms.

In the introductory papers read today the most important statement was that made by Andren referring to the instability of the hip in the first week of life. This is where the age-limit should be set. If the affected joint is treated and reduced within the first week of life the course will be very favourable. Immobilization in the first week of life is of greatest importance. Towards the age of two or three weeks the clinical diagnosis will be difficult and this is where radiographs will play a part. After the age of three weeks examination under anaesthesia will often be necessary. The joint must then be dislocated so as to verify the abnormality. The answer to Weismann's extremely pessimistic report from Israel about their failure of treatment in a von Rosen splint is very likely that the babies were not examined in their first week of life or that the splint was not applied properly. In fact the reduction was not made immediately.

General discussion

COMPILED BY MAC FELLANDER STOCKHOLM

The main questions discussed at the symposium were

- 1 Clinical diagnosis and incidence
- 2 Treatment
- 3 X-ray examination
- 1 Secondary bone changes
- 1 Missed cases

1 Clinical diagnosis

JACOBSSON pointed out that Severin in his series published in 1911 reported an incidence of only 0.9 per mill. This figure would be representative of the incidence in Sweden. The Stockholm series at present amounting to 660—760 infants comprises about 2 per mill of the number of births. In the Uppsala series presented here the incidence was 20 per mill. It cannot be possible that Ortolani's sign was present in 20 per mill of the cases. This must be a matter of over diagnosis. Surely the figure includes insignificant clicks which have nothing to do with Ortolani's sign. The incidence must be of reasonable proportions. The criteria for the diagnosis should be stricter so that the materials can be compared.

This would also hold true for the assessment of the prognosis as regards secondary bone changes. In the Stockholm area the paediatricians have now learnt to recognize Ortolani's sign and most of the babies referred for treatment have shown the ridge phenomenon. This may account for the higher incidence of secondary bone changes in this series.

SILVERSTEIN stated that the incidence of 20 per mill reported in the Uppsala series relates not only to babies with Ortolani's sign but to all the babies referred to the Orthopaedic Department. Cases of suspected laxity or a positive provocation manoeuvre by Palmer's technique are also included.

HUSSEIN agreed with Jacobson that the paediatricians who carry out the systematic examination of hips in the newborn must be taught the way to demonstrate abnormal movement of the hip joint. When we achieve greater

It has been asserted that early treatment that is starting on the first or second day of life would prevent the development of the late changes in the head and neck of the femur with which we are concerned here. To verify this I have in co-operation with Alvin paediatrician at the Södersjukhuset during a period of just over one year treated every infant with a proven Ortolani's sign in a splint from its first or second day of life. When the mother left the maternity ward the baby was transferred to me for continued checkings and follow-ups. This means that there was no elimination of cases of spontaneously healing hip with Ortolani's sign as there had been in the reported material at this symposium. The other day I looked through the records of Alvin's and my series which by now is $1\frac{1}{2}$ to 2 years old and found that the said X-ray changes were present in 13 out of the 46 infants or in nearly one-third of the cases. In assessing this figure it should be remembered that during this period Alvin placed every child with clicking hips in a splint and so some babies were treated who according to the principles applied by me would have needed no treatment but merely observation.

General discussion

COMPILED BY MAC FELLANDER STOCKHOLM

The main questions discussed at the symposium were

- 1 Clinical diagnosis and incidence
- 2 Treatment
- 3 X ray examination
- 4 Secondary bone changes
- 5 Missed cases

I Clinical diagnosis

JACOBSSON pointed out that Severin in his series published in 1941 reported an incidence of only 0.9 per mill. This figure would be representative of the incidence in Sweden. The Stockholm series at present amounting to 600-700 infants comprises about 2 per mill of the number of births. In the Uppsala series presented here the incidence was 20 per mill. It cannot be possible that Ortolani's sign was present in 20 per mill of the cases. This must be a matter of over diagnosis. Surely the figure includes insignificant clicks which have nothing to do with Ortolani's sign. The incidence must be of reasonable proportions. The criteria for the diagnosis should be stricter so that the materials can be compared.

This would also hold true for the assessment of the prognosis as regards secondary bone changes. In the Stockholm area the paediatricians have now learnt to recognize Ortolani's sign and most of the babies referred for treatment have shown the ridge phenomenon. This may account for the higher incidence of secondary bone changes in this series.

SEASTEDT-GOT stated that the incidence of 20 per mill reported in the Uppsala series relates not only to babies with Ortolani's sign but to all the babies referred to the Orthopaedic Department. Cases of suspected laxity or a positive provocation manoeuvre by Palmén's technique are also included.

HINCH agreed with Jacobsson that the paediatricians who carry out the systematic examination of hips in the newborn must be taught the way to demonstrate abnormal movement of the hip joint. When we achieve greater

It has been asserted that early treatment that is starting on the first or second day of life would prevent the development of the late changes in the head and neck of the femur with which we are concerned here. To verify this I have in co operation with Alvin paediatrician at the Sodersjukhuset during a period of just over one year treated every infant with a proven Ortolani's sign in a splint from its first or second day of life. When the mother left the maternity ward the baby was transferred to me for continued checkings and follow ups. This means that there was no elimination of cases of spontaneously healing hip with Ortolani's sign as there had been in the reported material at this symposium. The other day I looked through the records of Alvin's and my series which by now is $1\frac{1}{2}$ to 2 years old and found that the said X ray changes were present in 13 out of the 46 infants or in nearly one third of the cases. In assessing this figure it should be remembered that during this period Alvin placed every child with clicking hips in a splint and so some babies were treated who according to the principles applied by me would have needed no treatment but merely observation.

3 X ray examination

L. HULT did not believe that much was gained by X ray primarily. Of course it is all right when the examination is carried out by an experienced radiologist like Andren in Malmö but such expert radiological service is not available to every orthopaedic surgeon. There is also the risk that we will get the wrong information by the X ray examination and further the idea might gain ground among paediatricians and orthopaedists that the disorder should be diagnosed by X ray. If it could be proved to have any advantages X ray at birth should of course be used.

ANDREN replied that unless it can be properly performed X ray examination should of course be omitted. The radiologist must be interested in this abnormality. Most radiologists are not—they simply take a picture. He agreed with Hult that we are likely to miss cases if we rely on the radiograph.

HULT hoped that the interest in X ray examination of these children would by now have been stimulated and that the radiologists would acquire the particular technique.

HULT considered that this type of X ray examination differed from others in that the radiologists must be able to establish a clinical diagnosis which they should then verify by X ray.

ANDREN had had one case in which the paediatrician had suspected hip instability but in which he was not able to feel any slipping movement clinically whereas X ray showed genuine dislocation.

FÄRBER with experience from Lund and Uddevalla where patients are referred from large regional hospitals has managed without primary X ray examination.

FÄRBER raised the question whether the reported dislocation provoked at X ray examination might injure the epiphyseal nucleus. He emphasized that the infants are subjected to so many examinations first by the paediatrician then by the orthopaedist and finally by the radiologist.

FÄRBER did not think that X ray was necessary primarily if there is clear clinical evidence of a true Ortolani's phenomenon. But up to now their policy has been to examine every infant by X ray at the first visit. In some cases dislocation was diagnosed clinically when X ray was negative. These infants were of course treated. Jacobsson believes however that checking by X ray is necessary later on in his cases it is usually made when the children begin to walk. This would apply to uncomplicated cases but as soon as there is some doubt or when there is limitation of abduction films are taken earlier. The present routine is to use radiography at the age of 12—18 months and then at the age of 3 years and 6 years. This has meant a fairly low reduction of the X ray dose.

uniformity with respect to the diagnosis the calculations of the incidence will be more consistent throughout the country. It is not possible that the incidence can vary so much as today's reports would suggest. One could accept a wider field of indications if one knew for certain that the treatment would not cause any damage.

2 Treatment

The subject of discussion was how and for how long the babies should be immobilized. According to reports at the symposium a Frejka pillow was used in Gothenburg and Uppsala and von Rosen's splint in the other orthopaedic departments.

HIRSCH, who had experience with the Frejka pillow, brought up the question whether this method might involve the risk of dislocation being caused during the course of treatment. On the other hand he asked if the rigid immobilization in a von Rosen splint could give rise to disturbances in the growth of the bone nuclei.

VON ROSEN emphasized that it was important to ensure that the joint head be kept in place for the first few weeks and he did not think that this could always be done with the Frejka pillow in active babies. As regards splintage he believed that it should not be too rigid but should allow movement of the legs which should be held abducted in such a position that the head of the femur is centered towards the acetabulum. The splint should not be left on for more than three months.

JACOBSSON mentioned that his patients had been treated with a slight modification of the von Rosen splint and that the splintage had probably been too rigid. In view of the high incidence of secondary bone changes in his series less rigid splintage was now used.

LINDSTROM considered that the splint should be worn continuously. It should not be removed for bathing the baby. Within his region where the paediatricians had earlier had the care of the cases and issued instructions he had seen redislocations which he believed were attributable to the practice of frequent removal of the splint.

FELLANDER asked von Rosen whether he believed that it was precarious to exclude certain cases from treatment as was done by Jacobsson's method. Such a decision would require great experience on the part of the examiner and the policy should perhaps not be recommended for general use.

VON ROSEN replied that it was difficult to decide which babies needed treatment and as for himself he did not want to take the risk of leaving a baby untreated.

3 X ray examination

L. HULT did not believe that much was gained by X ray primarily. Of course it is all right when the examination is carried out by an experienced radiologist like Andren in Malmö but such expert radiological service is not available to every orthopaedic surgeon. There is also the risk that we will get the wrong information by the X ray examination and further the idea might gain ground among paediatricians and orthopaedists that the disorder should be diagnosed by X ray. If it could be proved to have any advantages X ray at birth should of course be used.

ANDREN replied that unless it can be properly performed X ray examination should of course be omitted. The radiologist must be interested in this abnormality. Most radiologists are not—they simply take a picture. He agreed with Hult that we are likely to miss cases if we rely on the radiograph.

HILSCH hoped that the interest in X ray examination of these children would by now have been stimulated and that the radiologists would acquire the particular technique.

HULT considered that this type of X ray examination differed from others in that the radiologists must be able to establish a clinical diagnosis which they should then verify by X ray.

ANDREN had had one case in which the paediatrician had suspected hip instability but in which he was not able to feel any slipping movement clinically whereas X ray showed genuine dislocation.

FORSUM with experience from Lund and Uddevalla where patients are referred from large regional hospitals has managed without primary X ray examination.

LINDBSTRÖM raised the question whether the repeated dislocation provoked at X ray examination might injure the epiphyseal nucleus. He emphasized that the infants are subjected to so many examinations first by the paediatrician then by the orthopaedist and finally by the radiologist.

JACOBSSON did not think that X ray was necessary primarily if there is clear clinical evidence of a true Ortolani's phenomenon. But up to now their policy has been to examine every infant by X ray at the first visit. In some cases dislocation was diagnosed clinically when X ray was negative. These infants were of course treated. Jacobsson believes however that checking by X ray is necessary later on in his cases it is usually made when the children begin to walk. This would apply to uncomplicated cases but as soon as there is some doubt or when there is limitation of abduction films are taken earlier. The present routine is to use radiography at the age of 12—18 months and then at the age of 3 years and 6 years. This has meant a fairly great reduction of the X ray dose.

uniformity with respect to the diagnosis the calculations of the incidence will be more consistent throughout the country. It is not possible that the incidence can vary so much as today's reports would suggest. One could accept a wider field of indications if one knew for certain that the treatment would not cause any damage.

2 Treatment

The subject of discussion was how and for how long the babies should be immobilized. According to reports at the symposium a Frejka pillow was used in Gothenburg and Uppsala and von Rosen's splint in the other orthopaedic departments.

HINSCH who had experience with the Frejka pillow brought up the question whether this method might involve the risk of dislocation being caused during the course of treatment. On the other hand he asked if the rigid immobilization in a von Rosen splint could give rise to disturbances in the growth of the bone nuclei.

VON ROSEN emphasized that it was important to ensure that the joint head be kept in place for the first few weeks and he did not think that this could always be done with the Frejka pillow in active babies. As regards splintage he believed that it should not be too rigid but should allow movement of the legs which should be held abducted in such a position that the head of the femur is centered towards the acetabulum. The splint should not be left on for more than three months.

JACOBSSON mentioned that his patients had been treated with a slight modification of the von Rosen splint and that the splintage had probably been too rigid. In view of the high incidence of secondary bone changes in his series less rigid splintage was now used.

LINDSTROM considered that the splint should be worn continuously. It should not be removed for bathing the baby. Within his region where the paediatricians had earlier had the care of the cases and issued instructions he had seen redislocations which he believed were attributable to the practice of frequent removal of the splint.

FILIVANDER asked von Rosen whether he believed that it was precarious to exclude certain cases from treatment as was done by Jacobsson's method. Such a decision would require great experience on the part of the examiner and the policy should perhaps not be recommended for general use.

VON ROSEN replied that it was difficult to decide which babies needed treatment and as for himself he did not want to take the risk of leaving a baby untreated.

3 X ray examination

I HULT did not believe that much was gained by X ray primarily. Of course it is all right when the examination is carried out by an experienced radiologist like Andren in Malmö but such expert radiological service is not available to every orthopaedic surgeon. There is also the risk that we will get the wrong information by the X ray examination and further the idea might gain ground among paediatricians and orthopaedists that the disorder should be diagnosed by X ray. If it could be proved to have any advantages X ray at birth should of course be used.

ANDREN replied that unless it can be properly performed X ray examination should of course be omitted. The radiologist must be interested in this abnormality. Most radiologists are not—they simply take a picture. He agreed with Hult that we are likely to miss cases if we rely on the radiograph.

HILSEN hoped that the interest in X ray examination of these children would by now have been stimulated and that the radiologists would acquire the particular technique.

HULT considered that this type of X ray examination differed from others in that the radiologists must be able to establish a clinical diagnosis which they should then verify by X ray.

ANDREN had had one case in which the paediatrician had suspected hip instability but in which he was not able to feel any slipping movement clinically whereas X ray showed genuine dislocation.

IMMERS with experience from Lund and Uddevalla where patients are referred from large regional hospitals has managed without primary X ray examination.

JACOBSSON raised the question whether the reported dislocation provoked at X ray examination might injure the epiphyseal nucleus. He emphasized that the infants are subjected to so many examinations first by the paediatrician then by the orthopaedist and finally by the radiologist.

JACOBSSON did not think that X ray was necessary primarily if there is clear clinical evidence of a true Ortolani's phenomenon. But up to now their policy has been to examine every infant by X ray at the first visit. In some cases dislocation was diagnosed clinically when X ray was negative. These infants were of course treated. Jacobsson believes however that checking by X ray is necessary later on in his cases it is usually made when the children begin to walk. This would apply to uncomplicated cases but as soon as there is some doubt or when there is limitation of abduction films are taken earlier. The present routine is to use radiography at the age of 12—18 months and then at the age of 3 years and 6 years. This has meant a fairly great reduction of the X ray dose.

SCHELLER described the routine in Gothenburg where the babies are examined by X-ray at birth then at the age of six weeks and three months thereafter repeated examinations are made if required depending upon the clinical course. When it is of interest to study the growth of the bone nucleus the X-ray examination is sometimes repeated.

RIBBING considered that too little is known about the hazards of X-ray examination and that the greatest caution should be recommended. This was the reason why so far he has not unlike Andren in Malmö applied a more thorough examination schedule but he will try it as he expects shortly to have at his disposal an X-ray apparatus which will permit substantial reduction of the dose by taking the pictures direct from an image intensifier with checking on the television screen.

ANDREX gave a report of the dose measurements made at the Institute of Radiophysics by which it has been found that the radiation dose for one exposure equals one week of background radiation provided that the newborn infant is placed direct on the plate holder and that a high speed film and large film-to-tube distance are used. The risk of genetic injury is greater at X-ray of the pelvis in a 20 year old patient. The radiation in this case will be at least 100 times as high as that to the newborn baby. A newborn baby if anybody can be subjected to X-ray examination without any risk of genetic injury. This is because the dose to the gonads is so small in comparison with that used for larger objects. If we were to hesitate to use X-ray in examining the newborn we would not dare to make any X-ray examinations whatsoever.

4 Secondary bone changes

HILSEN referred to animal experiments which showed that an abnormal position in the hip joint can result in disturbances of the growth of the nuclei and raised the question whether rigorous abduction treatment could involve the risk of such disturbances.

SEVASTYANOV brought up the question of the association between the mode of immobilization and the occurrence of bone changes. In the Uppsala series a Frejka pillow was used exclusively. Osteochondrosis of the capital epiphysis was seen in only one case. In the Stockholm series the infants were placed in a von Rosen splint and such changes were seen much more frequently.

GELLANDER drew attention to a study in children by Hnevalovsky and his co-workers which was presented at a round table conference at the SICOT congress in Paris 1966. The author observed cessation of arterial blood flow to the femoral head at extreme abduction.

VON ROSEN believed that the frog position is neither dangerous nor unphysiological in the first three months of life. He was surprised at the numerous secondary bone changes that were seen in the Stockholm series and pointed out the necessity of finding the reason as well as the importance of a continuous follow up of all series.

5 Missed cases

In this part of the discussion the subject was cases of hip dislocation which was not discovered by routine examination of the hip joint in the maternity departments. As regards the diagnosis Jacobsson emphasized that the examination should be made with the baby lying flat on its face with a view to detecting any limitation of abduction. If this was present particularly if it was noted on one side only, dislocation of the hip could be strongly suspected. With such an examination routinely of infants in their second or third month the number of missed cases of hip dislocation should be reduced. If the hip cannot be abducted to about 60° an X-ray examination should be performed and at this age it can give definite information as to the presence or absence of dislocation.

As regards treatment FRANKLIN stated that infants in whom the dislocation is detected at the age of three to six months should also be treated by mild reduction with traction in a position of abduction—inward rotation—that is the method which nowadays is fairly generally recommended in reduction of dislocation in older children. With this mild reduction the risk of circulatory disorders in the femoral head is smaller. Manipulations under anaesthesia and immobilization in a frog position should therefore not be used. Tellander mentioned that he had seen a patient whose dislocation was detected at the age of six months and who had been treated elsewhere in the ordinary frog position. The dislocation could not be corrected in this position. Arthrography with checking on the roentgen television screen showed that it became corrected when the leg was held in a position of abduction—inward rotation and dislocated in the frog position. In such cases arthrography would be useful in showing how to adjust the leg to obtain a good position of the femoral head. The examination must be carried out under anaesthesia but does not involve any traumatic manipulation. The use of an image intensifier ensures a low radiation dose. There is no reason to perform arthrography in uncomplicated cases. The arthrograms in the Stockholm series were undertaken to display the anatomy in normal and pathological cases.

VON ROSEN had very limited experience of missed cases. In the Malmö series from 1952–1965 there were three cases in which dislocation was detected when the children had begun to walk. He had personally treated

two of them by closed reduction under anesthesia and subsequent immobilization in plaster by Lorenz's method. The treatment had offered no difficulties. The acetabular roof had developed satisfactorily in both cases and no epiphyseal damage had occurred. The third case had been treated in the same way elsewhere. But the acetabular roof had not developed equally satisfactorily, but clinically the condition has been satisfactory up to now.

Hirsch also uses traction as the primary measure. If this fails open reduction is carried out, by which he has found that the tendon of psoas acts as an obstacle to the reduction together with the joint capsule, possibly the limbus. The tendon of psoas is divided and on splitting the capsule it is found that the head of the femur can easily be made to slip into the acetabulum. The psoas tendon is then transferred in front to the great trochanter, thus assuming the ability of inward rotation. If necessary a shelf operation is made in connection with the reduction.

Introduction

Intramedullary nailing with solid bars of bone ivory or metal has been used sporadically for the fixation of diaphyseal fractures in long bones since the end of the 19th century. For literature review see Kuntscher 1962.

The Rush brothers introduced in 1927 curved flexible solid steel pins for intramedullary osteosynthesis. In the fixation of diaphyseal fractures with these pins an elastic three point fixation is produced which however often allows relatively large movements in the fracture line. The mechanical stability of the osteosynthesis is often inadequate. As a rule therefore further complementary external fixation is required.

In 1940 Kuntscher introduced a new principle of osteosynthesis with a steel nail which was initially V-shaped but was later given the shape of a clover leaf. The nail could be compressed elastically from the sides. Kuntscher intended that it should be squeezed against the cortex inside the medullary cavity. In order to obtain stable fixation the nail has to be pressed firmly in the medullary cavity in both the proximal and distal fracture fragment. With hour glass shaped medullary cavities this means that the nail gives adequate fixation only in relatively transverse fractures within the narrowest area of the diaphysis.

Rigid fixation preferably stable enough for weight bearing, gives important advantages by allowing earlier mobilization of the patient and thus more rapid restoration of the general state of health with a decreased risk of thrombosis and renal calculi as a result. As regards local conditions of the affected limb there will be reduced muscular atrophy, reduced periarthritic fibrosis and oedema and more rapid removal of breakdown products from the fracture region.

In order to increase the possibilities of osteosynthesis of diaphyseal fractures with an intramedullary nail sufficiently stable for weight bearing Kuntscher developed in 1950 hand-operated reamers for widening the medullary cavity and in 1954 electrically driven reamers on a flexible axis which can be threaded over a guide wire which is inserted into the medullary cavity. By enlarging the medullary cavity space is created for a nail of such a diameter that it can take up the mechanical forces when weight is placed on the limb. In this way the risk is also avoided of the nail becoming wedged in the medullary cavity and splitting the cortex or separating

Introduction

Intramedullary nailing with solid bars of bone ivory or metal has been used sporadically for the fixation of diaphyseal fractures in long bones since the end of the 19th century. For literature review see Kuntscher 1962.

The Rush brothers introduced in 1927 curved flexible solid steel pins for intramedullary osteosynthesis. In the fixation of diaphyseal fractures with these pins an elastic three point fixation is produced which however often allows relatively large movements in the fracture line. The mechanical stability of the osteosynthesis is often inadequate. As a rule therefore further complementary external fixation is required.

In 1940 Kuntscher introduced a new principle of osteosynthesis with a steel nail which was initially V shaped but was later given the shape of a clover leaf. The nail could be compressed elastically from the sides. Kuntscher intended that it should be squeezed against the cortex inside the medullary cavity. In order to obtain stable fixation the nail has to be pressed firmly in the medullary cavity in both the proximal and distal fracture fragment. With hour glass shaped medullary cavities this means that the nail gives adequate fixation only in relatively transverse fractures within the narrowest area of the diaphysis.

Rigid fixation preferably stable enough for weight bearing gives important advantages by allowing earlier mobilization of the patient and thus more rapid restoration of the general state of health with a decreased risk of thrombosis and renal calculi as a result. As regards local conditions of the affected limb there will be reduced muscular atrophy, reduced periarticular fibrosis and oedema and more rapid removal of breakdown products from the fracture region.

In order to increase the possibilities of osteosynthesis of diaphyseal fractures with an intramedullary nail sufficiently stable for weight bearing Kuntscher developed in 1950 hand-operated reamers for widening the medullary cavity and in 1954 electrically driven reamers on a flexible axis which can be threaded over a guide wire which is inserted into the medullary cavity. By enlarging the medullary cavity space is created for a nail of such a diameter that it can take up the mechanical forces when weight is placed on the limb. In this way the risk is also avoided of the nail becoming wedged in the medullary cavity and splitting the cortex or separating

the fracture fragments by wedging in the distal fragment. By enlarging the medullary cavity in the middle part of the bone the nail can be held fast along a greater proportion of its length than is otherwise possible. Less force is required for driving home the nail, which probably means a reduced risk of fat embolism.

The pressure conditions in the distal metaphysis of the tibia were studied by Wehner (1968) with closed reaming and nailing of fractures of the tibial diaphysis in man. He found that 5–8 days after the fracture the medullary cavity pressure was 9–10 mm Hg. When the medullary cavity was opened with an awl, its pressure rose to 20–25 mm Hg within a short time. Closed reduction resulted in the same degree of pressure increase. When the guide wire was first inserted in the medullary cavity a pressure increase of about 40 mm Hg was obtained. On subsequent reaming there was a maximal pressure increase of 120 mm Hg. The pressure increase was greatest when the reaming began in the distal fragment and was greater the wider the calibre of the reamer. When the reamer was withdrawn from the medullary cavity, a negative pressure of about 100 mm Hg was recorded. On driving in the nail, practically no measurable pressure increase was obtained. With an open operation on the fracture a smaller pressure increase was obtained than with a closed technique. Operations on the femur gave similar results to those on the tibia.

Since 1964 we have employed Kuntscher's instrument for reaming of the medullary cavity and have now used it on about 30 fresh fractures of the femur and in a few pseudarthroses. After about 1 week of preoperative extension therapy the operation was performed on an extension table under radiographic control with a television monitor. For two reasons the fracture was reduced by the open technique: through an incision lateral to vastus lateralis firstly to provide a possibility of more exact reduction and secondly to counteract the pressure increase in the medullary cavity and in the fracture haematoma associated with the reaming of the medullary cavity. The medullary cavity was reamed from the tip of the greater trochanter using short reaming stages and with the least possible pressure against the reamer. The calibre of the reamer was increased stepwise by $\frac{1}{8}$ –1 mm each time from 10 mm. The reaming was discontinued when both fracture fragments had been adequately reamed. A nail of greater diameter than 11.5 mm and $\frac{1}{8}$ –1 mm narrower than the widest reamer was chosen. The length of the nail was determined by measurement on the television screen of the guide wire which had been inserted in the medullary cavity on reaming. In fractures on the distal part of the middle third of the bone the nail was inserted to about 1 cm above the intercondylar fossa to be secured there in the cancellous bone. Proximally the nail should extend no higher than to

about 1/2 cm above the tip of the trochanter. Large intermediate fragments were secured to the bone by cerclage and the cerclage wires were removed within 3-4 months after the operation. The periosteal blood supply of the intermediate fragment was maintained as far as possible. The clinical results of the operations have been promising. The main advantage of the method, namely that the patient can usually put full weight on the limb within 2 weeks postoperatively, has been fully utilized. A more detailed report of the clinical results will be published elsewhere.

The periosteal cuff of callus was always several cm wide and the callus mass was assessed as considerable. Periosteal callus was visualized as a thin cloud-like shadow 3-4 weeks after the operation. The callus tissue showed its maximal extent on the radiograph about 6 weeks after the operation. After this time there was usually no increase in the amount of callus.

Within the area in the vicinity of the fracture where, by reaming, the cortex had become greatly thinned—in some cases to half of its previous thickness—the periosteal callus tissue does not at first become attached to the thinned bone, but bridges this area. An area of low density is then seen on the radiograph between the callus tissue and the underlying bone, which is probably totally avascular and necrotic. After some months this bone becomes clearly eroded from the periosteal side and seems to be largely replaced by periosteal callus.

An intermediate fragment in which the periosteal circulation is retained and which is fixed into the osteosynthesis by cerclage is covered by a large amount of periosteal callus, which seems to become attached to the fragment from the beginning except within a narrow zone nearest to the fracture gaps. This finding is considered by Charnley (1968) to be a sign of ischaemia of the fracture ends.

In some younger patients the periosteal callus formation was not only localized to the fracture area but was also found as a thin cuff of bone around the greater part of the diaphysis.

The fracture gap was often seen radiographically to be still open 6 months after the operation.

A large amount of periosteal callus in a fracture is usually due to instability of the fracture (Karlinger and Sas 1961; Kuntscher 1962; Müller *et al.* 1965). Müller *et al.* in the AO group consider every radiographically visible periosteal callus formation occurring during the healing of a fracture fixed with a compression plate or compression screws as a sign of instability of the fracture. According to Böhler (1948) and Geiser (1967) in intramedullary nailing of diaphyseal fractures considerable periosteal callus formation may be due to the fact that the limb bears weight to a more normal extent than with other methods of osteosynthesis.

the fracture fragments by wedging in the distal fragment. By enlarging the medullary cavity in the middle part of the bone the nail can be held fast along a greater proportion of its length than is otherwise possible. Less force is required for driving home the nail which probably means a reduced risk of fat embolism.

In some younger patients the periosteal callus formation was not only localized to the fracture area but was also found as a thin cuff of bone around the greater part of the diaphysis.

The fracture gap was often seen radiographically to be still open 6 months after the operation.

A large amount of periosteal callus in a fracture is usually due to instability of the fracture (Karlinger and Sas 1961, Kuntzsch 1962, Muller *et al* 1965). Muller *et al* in the AO group consider every radiographically visible periosteal callus formation occurring during the healing of a fracture fixed with a compression plate or compression screws as a sign of instability of the fracture. According to Bohler (1948) and Geiser (1967) in intramedullary nailing of diaphyseal fractures considerable periosteal callus formation may be due to the fact that the limb bears weight to a more normal extent than with other methods of osteosynthesis.

The following factors oppose the view that in this material the development of periosteal callus was due essentially to instability

1 The callus tissue was already of the same extent when it first became visible radiographically after 3-4 weeks. No gradual increase, of the type seen in the development of a hypertrophic pseudarthrosis, was observed

2 No line of low density passing through the entire periosteal callus cuff was seen, as can be observed when there is considerable instability in a fracture

3 No bone resorption around the nail occurred until the fracture had healed

4 The patients were already free from pain in the fracture area about 1-2 days after the osteosynthesis

Reports have been published of several experimental studies on the reaction of the long bone after Kuntscher nailing and after evacuation of the medullary cavity. On the other hand no studies appear to have been made of the reaction of the long bone to the removal of bone from the endosteal surface by reaming of the medullary cavity

The aim of the present investigation was to study, by means of Indian ink angiography, bone labelling with tetracycline and histological methods the effect of reaming of the medullary cavity on the formation of callus and on the microcirculation in order to obtain an idea of the conditions of healing with this method of treatment. To investigate the effect *per se* the study was made of reaming of the medullary cavity of non fractured long bones

THE NORMAL VASCULAR SUPPLY OF THE TIBIAL
DIAPHYSIS IN THE RABBIT

The investigations of Langer in 1876 and the angiographic studies of Lexer *et al* in 1904 provided the basis for our understanding of the arterial vascular supply in the bone. The anatomy of the larger vessels is now well known while the microcirculation of the cortex is still obscure in many respects.

The diaphysis of the long bone obtains its arterial blood supply from three sources namely the nutrient artery, the metaphyseal arteries and the periosteal arteries. The nutrient artery of the tibia in the rabbit arises from the anterior tibial artery and perforates the tibia on the fibular side about 5 mm above the tibiofibular synostosis (Brookes & Harrison 1957, Gothman 1961). The artery passes obliquely through the cortex of the tibia in the distal tibial direction without giving off any branches to the cortex during its transit (de Marneffe 1953, Brookes 1964). In the medullary cavity the nutrient artery divides into ascending and descending branches which anastomose with the metaphyseal vessels (Gothman 1961). Branches from the nutrient artery supply the bone marrow. To the cortex pass both relatively wide arterioles which penetrate half the cortex and anastomose with vessels in the Haversian systems (Brookes 1964) and branches which penetrate the innermost layer of the cortex then to return to the medullary cavity and empty into venous sinusoids (Rohlich 1941, Brånemark 1959). In addition to these vessels there are branches which penetrate the entire cortex and directly connect the periosteal arterial system with the nutrient artery without interceding capillaries (Brookes & Harrison 1957, Gothman 1961). In practically all cases there is a secondary nutrient artery even though rudimentary (Gothman 1961). This perforates the tibia ventro-distally to the tibiofibular synostosis and supplies the fibular distal part of the tibial medullary cavity. Sometimes the descending branch of the primary nutrient artery is lacking. In these cases branches from the secondary nutrient artery supply the whole of the medullary cavity distal to the synostosis.

The metaphyseal arteries arise from the periosteal vascular plexus around the metaphysis and perforate the cortex with fairly wide branches in several places. The arteries send off branches within the metaphyseal area and

THE NORMAL VASCULAR SUPPLY OF THE TIBIAL
DIAPHYSIS IN THE RABBIT

The investigations of Langer in 1876 and the angiographic studies of Lexer *et al* in 1904 provided the basis for our understanding of the arterial vascular supply in the bone. The anatomy of the larger vessels is now well known while the microcirculation of the cortex is still obscure in many respects.

The diaphysis of the long bone obtains its arterial blood supply from three sources namely the nutrient artery, the metaphyseal arteries and the periosteal arteries. The nutrient artery of the tibia in the rabbit arises from the anterior tibial artery and perforates the tibia on the fibular side about 5 mm above the tibiofibular synostosis (Brookes & Harrison 1957, Gothman 1961). The artery passes obliquely through the cortex of the tibia in the distal tibial direction without giving off any branches to the cortex during its transit (de Marneffe 1953, Brookes 1964). In the medullary cavity the nutrient artery divides into ascending and descending branches which anastomose with the metaphyseal vessels (Gothman 1961). Branches from the nutrient artery supply the bone marrow. To the cortex pass both relatively wide arterioles which penetrate half the cortex and anastomose with vessels in the Haversian systems (Brookes 1964) and branches which penetrate the innermost layer of the cortex then to return to the medullary cavity and empty into venous sinusoids (Rohlich 1941, Branemark 1959). In addition to these vessels there are branches which penetrate the entire cortex and directly connect the periosteal arterial system with the nutrient artery without interceding capillaries (Brookes & Harrison 1957, Gothman 1961). In practically all cases there is a secondary nutrient artery even though rudimentary (Gothman 1961). This perforates the tibia ventro-distally to the tibiofibular synostosis and supplies the fibular distal part of the tibial medullary cavity. Sometimes the descending branch of the primary nutrient artery is lacking. In these cases branches from the secondary nutrient artery supply the whole of the medullary cavity distal to the synostosis.

The metaphyseal arteries arise from the periosteal vascular plexus around the metaphysis and perforate the cortex with fairly wide branches in several places. The arteries send off branches within the metaphyseal area and

anastomose with branches of the nutrient artery, resulting in the formation of a medullary arterial system (Brookes & Harrison, 1957, Gothman, 1961, Trueta & Caladías 1964) The growing epiphysis has a separate vascular supply After closure of the epiphysis anastomoses occur between the metaphyseal and the epiphyseal arteries (Trueta & Caladías, 1964) According to Gothman (1961) the anastomoses with the vessels in the distal epiphysis are wide but narrow with the vessels in the proximal epiphysis

The periosteal arterial system of the diaphysis consists of six or seven longitudinal arteries, which run along the entire length of the diaphysis and unite the arterial periosteal plexus at the metaphyses (Morgan 1959) In growing bones branches pass from the periosteal arteries to a capillary network located in the osteogenic layer of the periosteum immediately adjacent to the bone surface (Brookes 1964) This periosteal capillary network is in addition supplied with a large number of small vessel branches from musculature attached to the bone The periosteal capillary network communicates with the vessels in the Haversian canals via several narrow vessels which arise from the network almost at right angles These vessels which penetrate the outer cortex are most profuse nearest to the metaphyses (Morgan 1959 Trueta 1963, Gothman 1961)

The main venous vessel in the rabbit tibia consists of a thin walled canal located in the centre of the medullary cavity This canal is about 10 times wider than the nutrient artery (Brookes 1964) According to Morgan (1959) there are two principal veins in the distal part of the tibia which unite just below the middle of the tibia From this central vein radiate like spokes of a wheel a large number of venous sinusoids into which intracortical veins and medullary vessels empty The central vein is emptied partly through an emissary foramen situated inferiorly anteriorly to the entrance of the secondary nutrient artery and partly through several small veins especially in the metaphyseal areas, to veins outside the bone

The vessels in the diaphyseal cortex lie in bone canals the diameters of which are 10–20 μ (Branemark, 1959) Brookes (1964) states that within the periosteally formed bone in young adult rabbits the bone canals converge towards the primary ossification centre of the shaft In the endochondrally formed bone the bone canals show a mainly longitudinal course Numerous transverse anastomoses are found between the bone canals The intracortical canals tend to be wider towards the endosteal than towards the periosteal surface (Cohen & Harris 1958) The bone canals usually contain one vessel which consists of a single endothelial tube of constant diameter even after repeated divisions and anastomoses (Brookes 1964) According to Branemark (1959) the diameter of this capillary is 7–8 μ On vital microscopy of the endosteal part of the cortex in the rabbit fibula

Branemark (1959) found in some intracortical canals two vessels with different flow rates and opposite flow directions. Trueta (1963) found on ultraviolet microscopy of subperiosteal bone from the rabbit after injection of tetracycline intracortical canals containing two vessels one of which he considered to be a precapillary and the other a vein. Brookes (1964) observed further that in the endosteal part of the cortex there was a relatively small number of wide canals which contained precapillaries.

There is disagreement between different investigators as to which parts of the diaphyseal cortex in the rabbit are normally supplied by the different arterial systems. The various observations have been made by histological and angiographic studies (de Marneffe 1951, 1953; Brookes & Harrison 1957; Morgan 1959; Gothman 1961; Trueta 1963; Trueta & Caladias 1964) and by vital microscopic investigations (Brånemark 1959). The circulation in the cortex is described by Brookes (1964) as mainly centrifugal. According to Brookes the cortex is supplied with blood from branches of the nutrient artery in the medullary cavity which penetrate half the cortex and anastomose there with the capillary system in the Haversian canals. Depending upon the pressure conditions in the medullary cavity and in the veins outside the bone the blood flows from the central parts of the cortex in a centrifugal direction to the periosteal vessels or in a central direction to the venous system of the medullary cavity. According to Rohlich (1941) the majority of the veins of the compact bone empty into the sinusoids of the medullary cavity.

The vessels in the subperiosteal bone are considered by Brookes (1964) to be solely efferent veins. This opinion is shared by Brookes & Harrison (1957), McAuley (1958), Macnab (1958), Gustilo *et al* (1964) and Harrison (1966) and is based principally on angiographic studies using a suspension of fine grained barium sulphate (Mikropack) as contrast medium. According to Brookes & Harrison (1957) however Mikropack does not fill the vessels distal to the arterioles. This means that the capillaries leading from the periosteum into the cortex often remain empty of the perfusion medium (Trueta 1963). Morgan (1959) and Trueta (1963) consider that the outer one third of the cortex is supplied by periosteal vessels and the inner two-thirds by branches of the nutrient artery. De Marneffe (1953) claims that the cortex in the upper part of the tibial diaphysis in the rabbit is supplied mainly from medullary vessels and that in the middle part from both periosteal and medullary vessels while in the distal part of the diaphysis the vascular supply takes place almost exclusively from periosteal vessels. Communications between the periosteal and endosteal vascular systems via vessels which are wider than capillaries and which pass through the entire cortex have been shown by Brookes & Harrison (1957), Morgan (1959).

Gothman (1961) Trueta & Caladías (1964), Brookes (1964) and Rhinelander *et al* (1968), among others

From angiographic studies in the rabbit, Kookenberg (1963) summarizes the intracortical circulation as follows "the cortical network can be considered the capillary system of both the periosteal and the marrow vessels. The cortical network itself forms an anastomosis between periosteal and marrow vessels". He considered the most important source of blood supply to be the nutrient artery however. This opinion is shared by Rhinelander *et al* (1968), Kelly (1968) and others

THE EFFECT OF SELECTIVE OCCLUSION OF THE MAIN BLOOD VESSELS OF THE LONG BONE ON THE INTRACORTICAL AND MEDULLARY CIRCULATION

The long bone obtains its arterial blood supply from three vascular systems: the nutrient artery, the metaphyseal-epiphyseal arteries and the periosteal vessels. For understanding of the nutrition of bone after operations on the diaphyseal cortex, it is essential to know to what extent the different vascular systems can take over each others normal supply areas. Attempts have been made to clarify this question by selectively occluding in animals one or more of the vascular systems and then studying by histological and angiographic methods the extent of the necrosis which has occurred and the deficiency of vascular visualization in the tissue. Pressure measurements in the medullary cavity have also been made in an attempt to elucidate this problem.

Division of the Nutrient Artery

The nutrient artery has been divided outside the bone. For the blood supply to the bone, the periosteal and the metaphyseal-epiphyseal vessels then remain. Such studies were performed on the rabbit by Bragdon *et al* (1949) and by Trueta & Caladías (1964). On histological examination Bragdon *et al* found in the femur of young rabbits small areas of infarction in the medulla and also in the inner parts of the cortex. In some cases large areas of cortical necrosis were found. Trueta & Caladías studied the radius in young and adult rabbits by histological methods and by angiography with Mikropack. They reported normal visualization of the vessels in the medulla and cortex and histologically no necrosis was seen either in young or adult animals.

Ligation of the nutrient artery outside the bone was performed in the dog

tibia by Drinker *et al* (1922) On perfusion of the remaining vessels with Indian ink normal visualization of the intracortical and medullary vessels was obtained

Shaw (1964) ligated the nutrient artery in the femur of young cats with open epiphysis and found a pronounced fall in the intramedullary pressure and blood flow while in adult animals the operation resulted in only a slight reduction of the intramedullary pressure and blood flow Cuthbertson *et al* (1964) reported that ligation of the nutrient artery of the tibia and humerus in dogs caused an immediate and profound fall in the intramedullary pressure and it remained low for 1-3 hours in 9 out of 19 bones and for 4-22 days or more in the 10 other bones

Division of the Nutrient Artery Combined with Blockade of the Periosteal Cortical Circulation

After division of the nutrient artery and occlusion of the periosteal and cortical vascular communications only the metaphyseal-epiphyseal vessels remain for providing the arterial blood supply The function of the periosteal vessels will have been temporarily discontinued by the fact that the periosteum is lifted up from the cortex and then replaced against it Revascularization of the cortex from the periosteum is then not prevented Permanent occlusion of the periosteal-cortical communication has been brought about by placing teflon foil between the periosteum and bone after raising the periosteum from the cortex the teflon foil then preventing revascularization of the cortex from the periosteum Such studies have been performed on the rabbit by Foster *et al* (1951) and Trueta & Caladiaz (1964) After temporary occlusion of the periosteal circulation and division of the nutrient artery Foster *et al* found in the femur of young rabbits on histological examination total necrosis of both the bone marrow and the cortex In adult animals they obtained very varying results Thus in many animals both the bone marrow and the cortex remained normal Trueta & Caladiaz found in young rabbits after permanent occlusion of the communications between periosteum and cortex with division of the nutrient artery that the nutrient artery in the medullary cavity did not fill with Mikropack on angiography and that histologically there was total necrosis of both the bone marrow and the cortex In adult rabbits the nutrient artery filled with contrast medium inside the medullary cavity The bone marrow remained normal histologically but the outer and middle parts of the cortex became devitalized

Corresponding studies were performed on the dog by Johnson (1927) Brunschwig (1929) Larson *et al* (1961) and Silberman *et al* (1967) After

temporary occlusion of the periosteal cortical vascular communications and division of the nutrient artery in young dogs, Brunschwig found necrosis of the bone marrow and inner parts of the cortex on histological examination. Larson *et al* found almost complete filling of the intramedullary vessels with Mikropack on angiography and a fully viable cortex histologically, and Silberman *et al* observed almost total avascularity of the cortex on angiography with Mikropack seven days after the operation but a viable cortex on histological studies. This might be due to factors discussed on page 74.

After permanent occlusion of the communications between periosteum and cortex and simultaneous division of the nutrient artery in young dogs Larson *et al* found that in some cases the bone marrow lacked Mikropack-filled vessels while in other cases the vascular visualization was increased. The cortex remained viable in some cases, and was necrotic or partially necrotic in others. Silberman *et al* observed total necrosis of the bone marrow and cortex.

On temporary occlusion of the periosteal cortical communications and division of the nutrient artery in adult dogs Brunschwig and Larson *et al* found no damage to the bone marrow or cortex. On permanent occlusion of the periosteal-cortical communications and division of the nutrient artery also in adult dogs Larson *et al* observed some necrosis of the bone marrow while Silberman *et al* and Johnson found the marrow to be normal. Larson *et al* and Silberman *et al* both found a normal cortical circulation while Johnson observed necrosis of the outer two thirds of the cortex.

Blockade of the Periosteal Cortical Circulation

After blockade of the periosteal cortical circulation the nutrient artery and the metaphyseal vessels remain for vascular supply of the cortex. Trueta & Caladris (1964) found partial necrosis of the outer parts of the cortex after permanent blockade of the periosteal cortical circulation in the rabbit tibia. The bone marrow and remaining parts of the cortex remained viable.

Blockade of the Periosteal Cortical Circulation and of the Metaphyseal Vessels

After blockade of the periosteal cortical vascular communications and of the metaphyseal vessels the nutrient artery is solely responsible for supplying the diaphysis. The metaphyseal—epiphyseal vessels have been blocked by opening the medullary cavity in the metaphyses and scraping out the bone marrow. In order to obtain permanent blockade of the metaphyseal vessels the medullary cavity has been plugged with for example wax in the metaphyseal area.

After permanent blockade of the metaphyseal vessels in this way and permanent occlusion of the periosteal-cortical vessels with interposition of teflon Trueta & Caladras (1964) found normal visualization of the vessels of the bone marrow and of the inner $1/3-2/3$ of the cortex on angiography with Mikropack in tibiae of both young and adult rabbits. The vessels in the outer $1/3-2/3$ of the cortex did not fill with Mikropack and these parts of the cortex showed necrosis. Johnson (1927) after similar operations on the dog observed necrosis of the outer two-thirds of the cortex but otherwise normal cortex and medullary contents.

The function of the nutrient artery can also be studied by perfusion of the vessel. Perfusion with Indian ink of the nutrient artery alone without interference with the remaining vascular systems was performed by Drinker *et al* in 1922. After this procedure they obtained visualization of the entire cortical and medullary vascular systems and noted that Indian ink left the bone through periosteal vessels. Shum *et al* (1968) found on studying the arterial supply of the femur in young rabbits with strontium⁸ that the nutrient artery was responsible for 71% of the blood supply to the diaphysis including the bone marrow.

Division of the Nutrient Artery and Occlusion of the Metaphyseal Vessels

The possibility of the periosteal arteries to compensate for loss of the nutrient artery and metaphyseal vessels is of especial interest with regard to operations in the medullary cavity. Different investigators have obtained very divergent results in such studies which has probably been largely due to the different methods used. Trueta & Caladras (1964) divided the nutrient artery outside the tibia in young and adult rabbits and at the same time made a permanent break in the communication between the metaphyseal and diaphyseal vessels within the medullary cavity by scraping out the bone marrow in the metaphysis and plugging the cavity with wax. They found that on angiography with Mikropack the intracortical vessels were not visualized until about one week after the operation and also that the bone marrow and inner two-thirds of the cortex had become necrotic. Macnab (1958), McAuley (1958) and Gustilo *et al* (1964) considered after perfusion studies with Mikropack that the periosteal vessels were unable to supply any part of the cortex. Johnson (1927) found after obliteration of the medullary circulation in the tibial diaphysis of the dog that total necrosis of the bone marrow had occurred and necrosis of the inner half of the cortex. He also found that on Indian ink angiography the cortex was very little injected. De Marneffe (1951) claims that the periosteum in the distal part

temporary occlusion of the periosteal cortical vascular communications and division of the nutrient artery in young dogs Brunschwig found necrosis of the bone marrow and inner parts of the cortex on histological examination Larson *et al* found almost complete filling of the intramedullary vessels with Mikropack on angiography and a fully viable cortex histologically and Silberman *et al* observed almost total avascularity of the cortex on angiography with Mikropack seven days after the operation, but a viable cortex on histological studies This might be due to factors discussed on page 74

After permanent occlusion of the communications between periosteum and cortex and simultaneous division of the nutrient artery in young dogs, Larson *et al* found that in some cases the bone marrow lacked Mikropack filled vessels while in other cases the vascular visualization was increased The cortex remained viable in some cases, and was necrotic or partially necrotic in others Silberman *et al* observed total necrosis of the bone marrow and cortex

On temporary occlusion of the periosteal cortical communications and division of the nutrient artery in adult dogs Brunschwig and Larson *et al* found no damage to the bone marrow or cortex On permanent occlusion of the periosteal-cortical communications and division of the nutrient artery also in adult dogs Larson *et al* observed some necrosis of the bone marrow while Silberman *et al* and Johnson found the marrow to be normal Larson *et al* and Silberman *et al* both found a normal cortical circulation while Johnson observed necrosis of the outer two thirds of the cortex

Blockade of the Periosteal Cortical Circulation

After blockade of the periosteal cortical circulation the nutrient artery and the metaphyseal vessels remain for vascular supply of the cortex Trueta & Caladias (1964) found partial necrosis of the outer parts of the cortex after permanent blockade of the periosteal cortical circulation in the rabbit tibia The bone marrow and remaining parts of the cortex remained viable

Blockade of the Periosteal Cortical Circulation and of the Metaphyseal Vessels

After blockade of the periosteal cortical vascular communications and of the metaphyseal vessels the nutrient artery is solely responsible for supplying the diaphysis The metaphyseal—epiphyseal vessels have been blocked by opening the medullary cavity in the metaphyses and scraping out the bone marrow In order to obtain permanent blockade of the metaphyseal vessels the medullary cavity has been plugged with for example wax in the metaphyseal area

is no definite evidence that the periosteal vessels cannot take over the nutrition in part of the diaphyseal cortex

There seems thus to be no marked difference between the rabbit and dog with regard to the potentialities of the three different vascular systems for taking over each others circulatory regions

THE EFFECT OF SURGERY ON THE MEDULLARY CAVITY OF THE DIAPHYSIS OF THE LONG BONE

Partial Destruction of the Medullary Circulation

Surgery to the medullary cavity can disturb the medullary and cortical circulation to different degrees. On intramedullary nailing of the rabbit tibia *without fracture* Gothman (1961) found that remnants of the nutrient artery were often visualized in the medullary cavity on arteriography. During the first days after the operation he observed slight filling of the intracortical vessels with Mikropack contrast medium. Not until after 10 day were the intracortical vessels better visualized. The osteocytes in the cortex remained viable.

Trueta & Cavadias (1955) studied fractured radius in rabbits treated with intramedullary nailing and found on angiography with Mikropack that the medullary vessels were practically always completely destroyed. Even far from the fracture line necrosis of the inner third to two thirds of the cortex was observed histologically in both young and adult animals.

On intramedullary nailing of osteotomized rabbit tibiae Gothman (1961) often found remnants of the medullary arteries in the medullary cavity. The vascular filling in the cortex away from the fracture line was similar to that in tibiae subjected to intramedullary nailing but not fractured. In two out of 35 rabbits a long irregular area of periosteal callus was seen along both fracture fragments. On angiography of osteotomized tibiae in rabbits treated with intramedullary nailing using Mikropack + Berlin blue as contrast medium Koekenberg (1963) obtained a similar degree of visualization of the medullary vessels as Gothman (1961).

Rhinelanders *et al* (1967) performed osteotomy and intramedullary nailing of the ulna in dogs and found on angiography with Mikropack that the cortex in contact with the medullary nail showed reduced vascularity of the inner half to two-thirds while that which had no contact with the nail was vascularized.

Gustilo *et al* (1964) found on Mikropack angiography of osteotomized dog femurs treated with intramedullary nailing that the periosteal vessels did not penetrate the cortex to supply it.

of the rabbit tibia can supply the entire cortex Rhinelander & Baragry (1962) consider that the periosteal circulation of long bones can take over when the medullary circulation has been interrupted

Summary

The diaphysis of the long bone is supplied from the nutrient artery, the metaphyseal and the periosteal arteries. If one or more of these arteries is obliterated the remaining vessels will to varying extents take over their function.

The periosteal and the metaphyseal epiphyseal vessels are able together to supply both the bone marrow and the cortex when the nutrient artery has been divided. In growing animals the periosteal arteries are then of the greatest importance, while in adult animals, in which the epiphysis is closed, the most important vessels are the metaphyseal and epiphyseal arteries (Trueta & Caladias, 1964).

In young rabbits the metaphyseal vessels cannot alone supply the contents of the medullary cavity and the cortex even if revascularization of the cortex from the periosteum is not prevented. In young dogs the metaphyseal vessels protect the cortex from necrosis if revascularization from the periosteum is not rendered impossible, but if revascularization is prevented varying degrees of cortical necrosis occur. In both adult rabbits and adult dogs the metaphyseal epiphyseal vessels alone can essentially supply the contents of the medullary cavity and at least the inner parts of the cortex.

If only the nutrient artery remains and the periosteal-cortical circulation is permanently interrupted necrosis occurs in the outer third of the cortex but when teflon foil is interposed between the periosteum and cortex the venous outflow from the cortex is probably also affected and this can contribute to the cortical damage. Rhinelander *et al* (1968) has pointed out that a blocked cortical outflow can cause the occurrence of bone necrosis under a compression plate lying closely against the bone.

In cases where the periosteal vessels alone remain several investigators have found that the intracortical vessels are not visualized primarily on angiography with Mikropack. This has been considered to mean that no functioning vessels are present. Trueta (1963) pointed out however that a lack of visualization of the vascular system with Mikropack does not preclude the presence of a nutritive flow. When the medullary cavity of the metaphyses were plugged with wax in order to close off the metaphyseal circulation a pressure increase may have been produced in the medullary cavity which might have affected the circulation in the cortex. Thus there

dullary vessels The bone formation was most extensive over the areas where the medullary and intracortical circulation was most severely damaged (Axhausen & Bergmann 1937 Trueta & Cavadias 1955 de Marneffe 1951 Gustilo *et al* 1964 Richany *et al* 1965 Andersson 1965 Mital & Cohen 1966) Richany *et al* found that the amount of periosteal bone formation corresponded exactly with the extent of medullary removal The increased subperiosteal bone formation has been considered by Kuntscher (1957) to be due to local acidosis and by Trueta & Cavadias to periosteal hyperaemia over necrotic cortex Richany *et al* and Johnson (1966) considered that local stasis with oedema and periosteal anoxia was the cause of the periosteal bone formation while Zucman *et al* (1968) showed that medullary fragments were squeezed out through the cortex to the subperiosteal space and there gave rise to extensive formation of bone

The subsequent development of the periosteal callus tissue has been studied by Trueta & Caladiaz (1964) Richany *et al* (1965) and Zucman *et al* (1968) Trueta & Caladiaz found in young rabbits that the subperiosteal cells proliferated after 2 days that new bone was present after 4 days and that after 6 days there were new trabeculae subperiosteally After 12 days the new bone covers the whole ulnar surface of the radius In adult rabbits a thin smooth layer of lamellar bone was found subperiosteally after 6 weeks Richany *et al* observed in young adult cats early marked cellular proliferation with circumferential subperiosteal bone deposition involving the diaphyses A maximal amount of subperiosteal bone was seen after an observation time of 20 days and subsequently the bone mass gradually decreased Periosteal bone was transformed to mature Haversian compact bone

Zuchman *et al* (1968) studied growing rabbits after reaming of the medullary cavity without removing bone from the endosteal surface They found on radiographic examination that callus tissue was observed 15 days postoperatively and this tissue reached a maximal size on the 15th to 21st day In the centre of the callus cavities developed and in the periphery of the callus corticalization was observed Cavities in callus tissue were described by Falkenberg (1961) in osteotomies with intramedullary nailing in rabbits He observed the first cavity 30 days after the operation According to his photographic illustrations it would seem that the cavities were localized more and more centrally in the bone with increasing time postoperatively

Cortical Reaction

When a necrosis of the inner part of the cortex has occurred e.g. after operations in the medullary cavity the necrotic area is revascularized from

Gothman (1961) performed intramedullary nailing of osteotomized tibiae in monkeys. He found on angiography with Mikropack that the medullary arteries were less extensively damaged than in the rabbit. In monkeys also, he observed almost no filling of the intracortical vessels with contrast medium during the first week postoperatively.

Intramedullary nailing of osteotomized long bones in animals without an angiographic examination has been performed by several investigators including Kuntscher (1961) and Anderson (1965).

Total Destruction of the Medullary Circulation

If the medullary contents are removed the cortex is completely dependent upon the periosteal circulation for its nutrition. Such operations have been carried out on rabbits by Rohlich (1941), Branemark (1964) and Zucman *et al* (1968), on cats by Richany *et al* (1965) and on rats by Mital & Cohen (1966). In connection with this operation angiography has only been performed by Mital & Cohen. Rohlich removed the bone marrow of the diaphysis with gauze after dividing the bone through the metaphyses. Branemark removed the marrow through a groove sawn out on the anterior side of the bone. Richany *et al* washed out the marrow with salt solution and, after having put down a rotating stainless steel pin in the cavity brushed the medullary cavity with a pipe cleaner. He obtained massive necrosis of the cortex except within the very outermost layer. Mital & Cohen removed the medulla by several different methods including suction brushing with a baby-bottle brush and filling of the medullary cavity with agar, and found necrosis in the cortex on maximal injury.

After operations in the medullary cavity with partial or total destruction of the bone marrow typical reactions from the periosteum, cortex and medullary cavity are obtained.

Periosteal Reaction

On disturbance of the endosteal circulation the periosteum reacts with increased vascular filling and proliferation of the vessels (Trueta & Cavadias, 1955; Gothman 1961; Zucman *et al* 1968). Trueta & Cavadias consider that proliferation of the periosteal vessels is always accompanied by the formation of new bone. Despite considerable vascular proliferation in the periosteum after intramedullary nailing of non-fractured tibiae in rabbits Gothman found no new bone formation in the periosteum, however, except in a very few cases.

Increased periosteal new bone formation in the diaphysis of the long bone has been demonstrated by several investigators after destruction of the me-

dullary vessels. The bone formation was most extensive over the areas where the medullary and intracortical circulation was most severely damaged (Axhausen & Bergmann 1937 Trueta & Caladías 1955 de Marneffe 1951 Gustilo *et al* 1964 Richany *et al* 1965 Andersson 1965 Mital & Cohen 1966). Richany *et al* found that the amount of periosteal bone formation corresponded exactly with the extent of medullary removal. The increased subperiosteal bone formation has been considered by Kuntscher (1957) to be due to local acidosis and by Trueta & Caladías to periosteal hyperaemia over necrotic cortex. Richany *et al* and Johnson (1966) considered that local stasis with oedema and periosteal anoxia was the cause of the periosteal bone formation while Zucman *et al* (1968) showed that medullary fragments were squeezed out through the cortex to the subperiosteal space and there gave rise to extensive formation of bone.

The subsequent development of the periosteal callus tissue has been studied by Trueta & Caladías (1964) Richany *et al* (1965) and Zucman *et al* (1968). Trueta & Caladías found in young rabbits that the subperiosteal cells proliferated after 2 days that new bone was present after 4 days and that after 6 days there were new trabeculae subperiosteally. After 12 days the new bone covers the whole ulnar surface of the radius. In adult rabbits a thin smooth layer of lamellar bone was found subperiosteally after 6 weeks. Richany *et al* observed in young adult cats early marked cellular proliferation with circumferential subperiosteal bone deposition involving the diaphyses. A maximal amount of subperiosteal bone was seen after an observation time of 20 days and subsequently the bone mass gradually decreased. Periosteal bone was transformed to mature Haversian compact bone.

Zuchman *et al* (1968) studied growing rabbits after reaming of the medullary cavity without removing bone from the endosteal surface. They found on radiographic examination that callus tissue was observed 15 days postoperatively and this tissue reached a maximal size on the 15th to 21st day. In the centre of the callus cavities developed and in the periphery of the callus corticalization was observed. Cavities in callus tissue were described by Falkenberg (1961) in osteotomies with intramedullary nailing in rabbits. He observed the first cavity 30 days after the operation. According to his photographic illustrations it would seem that the cavities were localized more and more centrally in the bone with increasing time postoperatively.

Cortical Reaction

When a necrosis of the inner part of the cortex has occurred, e.g. after operations in the medullary cavity the necrotic area is revascularized from

Gothman (1961) performed intramedullary nailing of osteotomized tibiae in monkeys. He found on angiography with Mikropack that the medullary arteries were less extensively damaged than in the rabbit. In monkeys, also he observed almost no filling of the intracortical vessels with contrast medium during the first week postoperatively.

Intramedullary nailing of osteotomized long bones in animals without an angiographic examination has been performed by several investigators, including Kuntscher (1961) and Anderson (1965).

Total Destruction of the Medullary Circulation

If the medullary contents are removed, the cortex is completely dependent upon the periosteal circulation for its nutrition. Such operations have been carried out on rabbits by Rohlich (1941), Branemark (1964) and Zucman *et al* (1968), on cats by Richany *et al* (1965) and on rats by Mital & Cohen (1966). In connection with this operation, angiography has only been performed by Mital & Cohen. Rohlich removed the bone marrow of the diaphysis with gauze after dividing the bone through the metaphyses. Branemark removed the marrow through a groove sawn out on the anterior side of the bone. Richany *et al* washed out the marrow with salt solution and after having put down a rotating stainless steel pin in the cavity brushed the medullary cavity with a pipe cleaner. He obtained massive necrosis of the cortex except within the very outermost layer. Mital & Cohen removed the medulla by several different methods, including suction brushing with a baby bottle brush and filling of the medullary cavity with agar and found necrosis in the cortex on maximal injury.

After operations in the medullary cavity with partial or total destruction of the bone marrow, typical reactions from the periosteum, cortex and medullary cavity are obtained.

Periosteal Reaction

On disturbance of the endosteal circulation, the periosteum reacts with increased vascular filling and proliferation of the vessels (Trueta & Cavadias 1955, Gothman 1961, Zucman *et al* 1968). Trueta & Cavadias consider that proliferation of the periosteal vessels is always accompanied by the formation of new bone. Despite considerable vascular proliferation in the periosteum after intramedullary nailing of non-fractured tibiae in rabbits, Gothman found no new bone formation in the periosteum, however, except in a very few cases.

Increased periosteal new bone formation in the diaphysis of the long bone has been demonstrated by several investigators after destruction of the me

dullary vessels. The bone formation was most extensive over the areas where the medullary and intracortical circulation was most severely damaged (Axhausen & Bergmann 1937, Trueta & Cavadias 1955, de Marneffe 1951, Gustilo *et al* 1964, Richany *et al* 1965, Andersson 1965, Mital & Cohen 1966). Richany *et al* found that the amount of periosteal bone formation corresponded exactly with the extent of medullary removal. The increased subperiosteal bone formation has been considered by Kuntscher (1957) to be due to local acidosis and by Trueta & Cavadias to periosteal hyperaemia over necrotic cortex. Richany *et al* and Johnson (1966) considered that local stasis with oedema and periosteal anoxia was the cause of the periosteal bone formation while Zucman *et al* (1968) showed that medullary fragments were squeezed out through the cortex to the subperiosteal space and there gave rise to extensive formation of bone.

The subsequent development of the periosteal callus tissue has been studied by Trueta & Caladiaz (1964), Richany *et al* (1965) and Zucman *et al* (1968). Trueta & Caladiaz found in young rabbits that the subperiosteal cells proliferated after 2 days, that new bone was present after 4 days and that after 6 days there were new trabeculae subperiosteally. After 12 days the new bone covers the whole ulnar surface of the radius. In adult rabbits a thin smooth layer of lamellar bone was found subperiosteally after 6 weeks. Richany *et al* observed in young adult cats early marked cellular proliferation with circumferential subperiosteal bone deposition involving the diaphysis. A maximal amount of subperiosteal bone was seen after an observation time of 20 days and subsequently the bone mass gradually decreased. Periosteal bone was transformed to mature Haversian compact bone.

Zuchman *et al* (1968) studied growing rabbits after reaming of the medullary cavity without removing bone from the endosteal surface. They found on radiographic examination that callus tissue was observed 15 days postoperatively and this tissue reached a maximal size on the 15th to 21st day. In the centre of the callus cavities developed and in the periphery of the callus corticalization was observed. Cavities in callus tissue were described by Falkenberg (1961) in osteotomies with intramedullary nailing in rabbits. He observed the first cavity 30 days after the operation. According to his photographic illustrations it would seem that the cavities were localized more and more centrally in the bone with increasing time postoperatively.

Cortical Reaction

When a necrosis of the inner part of the cortex has occurred e.g. after operations in the medullary cavity the necrotic area is revascularized from

the viable outer part of the cortex (Phemister, 1930 Röhlich, 1941 Trueta & Cavadias, 1955, Kockenberg 1963 Ricany *et al* 1965, Rhinelander *et al* 1968) The channels in the viable part of the cortex become wider and contain more blood vessels (Axhausen & Bergmann, 1937 Brookes, 1960) Vessels with preceding osteoclasts, so-called cutting heads, bore channels through the necrotic bone in the direction towards the medullary cavity The bone channels then become gradually narrower behind the cutter head by the formation of bone on their walls (Schenk & Willenegger, 1963, Johnson 1966) In young animals, large, irregular resorption cavities can be formed in the necrotic bone (Axhausen & Bergmann, 1937, Richany *et al* 1965) but in adult animals small round cavities are formed (Johnson 1966) This rebuilding process also affects viable bone but the resorption cavities are smaller in viable than in necrotic bone (Axhausen & Bergmann, 1937)

In young adult cats the maximal reconstruction of the cortex takes place 40 days after disturbance of the endosteal circulation when the periosteal reaction is already declining (Richany *et al* 1965) Trueta & Cavadias (1955) found that in growing rabbits cortex two-thirds of which had primarily shown necrosis, was almost completely rebuilt after 7 weeks, while in adult animals necrotic areas were still present after 8 months Resorption in the inner part of the cortex was established radiographically after an observation time of 4 weeks (Trueta & Cavadias, 1955, Richany *et al* 1965) According to Phemister (1948) large necrotic areas in the cortex are never completely rebuilt Especially in older individuals, the reparative stimulus seems to become exhausted Axhausen & Bergmann (1937) consider that the cells from which new bone formation occurs in the necrotic bone areas arise from the periosteum or from the medullary cavity, while in the opinion of Trueta (1963) they arise from the vascular endothelium Other authors believe that the source of origin is the perivascular mesenchymal tissue (Brookes 1960) The amount of new bone that is formed to replace the degenerated necrotic bone is highly dependent upon the functional stimulus to which the limb is subjected (Phemister 1930) As a rule more bone is broken down within the zone than is reformed (Axhausen & Bergmann 1937)

Medullary Reaction

The healing processes in the medullary cavity after the evacuation of its contents have been studied by Röhlich (1941) Trueta & Caladias (1964) Branemark (1964) and Richany *et al* (1965) among others All these investigators give similar descriptions for these processes but the time course varies considerably After 3 days Branemark observed widening of the Haversian canals nearest to the medullary cavity and at the same time the

haematoma in the medullary cavity began to be organized Rohlich using histological methods observed bone formation in the medullary cavity after 14 days Trueta & Caladras noted some new vessels in the medullary cavity 9 days after operation Rohlich found that the bone bridges began to be resorbed within its peripheral areas 19 days after operation Branemark observed this 3 weeks after operation According to Richany *et al* the normal medullary structures were rebuilt after 160 days Rohlich observed that the vessels in the medullary cavity nearest to the residual avascular region were narrow while those around the bone bridges in the more peripheral area of the medullary cavity were wide and thin walled Trueta & Caladras found that in adult rabbits blood vessels did not invade the medullary cavity from the cortex until after 6 weeks and infarctions still persisted in the medullary cavity 6 months postoperatively

HISTOLOGICAL CHANGES ON NECROSIS OF CORTICAL BONE

When the blood circulation to bone tissue is occluded the bone dies in the course of a few days (Phemister 1948 Bonfiglio 1954) Woodhouse (1962) after occlusion of the circulation to the femoral head for 6 hours in the dog found total necrosis of the femoral head in 3 cases out of 6 After occlusion of the circulation for 12 hours he found total necrosis of the femoral head in all cases

Axhausen & Bergmann (1937) studied the development of bone necrosis and found that during the first week after the circulation to the cortical bone had been occluded no histologically visible changes occurred Later there was pyknosis of the osteocytic nuclei which became fragmented decreased in size and stained darker Axhausen & Bergmann considered that the recognition of pyknosis was rather difficult and required high magnification and very careful observation They also considered that the most reliable sign that the bone was necrotic was the presence of nucleus free osteocytic lacunae According to Axhausen & Bergmann the degeneration and removal of the pyknotic nucleus demands circulating tissue fluid The time it takes for the osteocytic nuclei in cortical bone to dissolve is dependent upon the thickness of the bone tissue and the penetration capacity of the vessels which force their way in and by which means the dissolution takes place According to Schenk (1969) osteocytic nuclei in cortical bone disappear about 2 weeks after bone necrosis In dead bone the nuclei disappear first from the surface and the layer beneath contains pyknotic osteocytic nuclei (Axhausen & Bergmann 1937) In ischaemia of cortical bone without total occlusion of the circulation the cells in the interstitial lamellae to which

the viable outer part of the cortex (Phemister, 1930, Rohlich 1941, Trueta & Cavadias, 1955, Kockenbergs 1963 Ricany *et al* 1965, Rhinelanders *et al* 1968) The channels in the viable part of the cortex become wider and contain more blood vessels (Axhausen & Bergmann 1937, Brookes 1960) Vessels with preceding osteoclasts, so-called cutting heads bore channels through the necrotic bone in the direction towards the medullary cavity The bone channels then become gradually narrower behind the cutter head by the formation of bone on their walls (Schenk & Willenegger, 1963, Johnson 1966) In young animals, large, irregular resorption cavities can be formed in the necrotic bone (Axhausen & Bergmann 1937, Richany *et al* 1965) but in adult animals small round cavities are formed (Johnson 1966) This rebuilding process also affects viable bone but the resorption cavities are smaller in viable than in necrotic bone (Axhausen & Bergmann, 1937)

In young adult cats the maximal reconstruction of the cortex takes place 40 days after disturbance of the endosteal circulation when the periosteal reaction is already declining (Richany *et al* 1965) Trueta & Cavadias (1955) found that in growing rabbits cortex, two-thirds of which had primarily shown necrosis, was almost completely rebuilt after 7 weeks while in adult animals necrotic areas were still present after 8 months Resorption in the inner part of the cortex was established radiographically after an observation time of 4 weeks (Trueta & Cavadias, 1955 Richany *et al*, 1965) According to Phemister (1948), large necrotic areas in the cortex are never completely rebuilt Especially in older individuals the reparative stimulus seems to become exhausted Axhausen & Bergmann (1937) consider that the cells from which new bone formation occurs in the necrotic bone areas arise from the periosteum or from the medullary cavity, while in the opinion of Trueta (1963) they arise from the vascular endothelium Other authors believe that the source of origin is the perivascular mesenchymal tissue (Brookes 1960) The amount of new bone that is formed to replace the degenerated necrotic bone is highly dependent upon the functional stimulus to which the limb is subjected (Phemister 1930) As a rule more bone is broken down within the zone than is reformed (Axhausen & Bergmann 1937)

Medullary Reaction

The healing processes in the medullary cavity after the evacuation of its contents have been studied by Rohlich (1941) Trueta & Cavadias (1964) Brånemark (1964) and Richany *et al* (1965) among others All these investigators give similar descriptions for these processes but the time course varies considerably After 3 days Brånemark observed widening of the Haversian canals nearest to the medullary cavity and at the same time the

Reaming, Brushing and Suction of the Medullary Cavity of the Rabbit Tibia

Material and Methods

Adult and growing non pregnant rabbits of different breeds and of both sexes were used for the experiments. The rabbit was chosen as the main experimental animal both because its tibia is sufficiently large to allow reaming of the medullary cavity and because a relatively large number of animals was required.

The information given by the breeders on the ages of the animals was not always reliable. The material was therefore divided into two groups of adult and growing animals according to whether the fibular epiphysis was found to be closed or not on radiographic examination which was performed at the end of the experiment. According to Heikel (1960) the epiphysis of the rabbit fibula closes at the age of 5-7 $\frac{1}{2}$ months and according to Geiser (1963) this takes place at 5 months.

Of 178 rabbits used 4 were used for determining the heat development and pressure conditions in the medullary cavity on reaming and brushing 22 for a study of intracortical fat and 24 for correlation of the amount of newly formed bone to the degree of traumatization of the cortex. From the remaining 128 animals which were used for general morphological studies after reaming 25 were excluded after fracture had occurred on the treated leg and 17 died for various reasons during the experimental period. The remaining 86 animals are presented in Table I.

Preliminary studies showed that the morphological changes which occurred could most suitably be recorded at observation times of 3 days and 1, 2, 4, 8 and 12 weeks. Large groups of animals were therefore studied at these observation times after operation and these were called the main experimental groups. In 61 of the 86 animals (28 adults and 33 growing animals) the medullary cavity of the left tibia was reamed while the right tibia served as a control. In order to obtain a larger amount of material for morphological studies both the left and right tibia were reamed in 25 animals (7 adults and 18 growing animals). In these cases the left tibia was used for fluorescence microscopic studies and the right tibia for angiographic and histological studies.

the nutrition is normally poorest die first, while the cells in the Haversian systems are still intact (Brookes 1960) On further deterioration of the blood supply the osteocytes in the remaining parts of the bone die, while the cells in the bone marrow and in the periosteal soft tissues can remain viable The osteocytes are thus very sensitive to anoxia (Halshofer 1937)

Bonfiglio (1954) found stainable osteocytic nuclei in the femoral head of the dog 2-3 weeks after total permanent occlusion of the circulation to the femoral head Catto (1965) obtained similar results in studies of the femoral head in man after medial femoral neck fractures, and Rokkanen *et al* showed in 1965 that histologically visible changes in the rabbit femoral head did not occur until 2-3 weeks after total occlusion of the circulation to the head

Other workers have found considerably more rapid removal of the osteocytic nucleus from necrotic cortical bone than the investigators referred to above Ham & Harris thus found in 1956 in fractures of cortical bone that the osteocytic lacunae at the fracture ends were already empty 2-3 days after the fracture Foster *et al* (1951) after ligation of the nutrient artery and stripping of the periosteum in the rabbit observed that the osteocytes in the cortex had faded already within the first 24 hours Within 3 days the osteocytic nuclei had disappeared except in some areas

Operation

The rabbits were anaesthetized with Nembutal[®] Abbot for veterinary use in a dose of about 30 mg/kg body weight which was given as an intravenous injection through an aural vein. Complementary injections of Nembutal[®] were given until the Achilles reflex was no longer present. The animal was strapped in the supine position on to a special sled formed operation table with the hip and knee joints flexed at 60°. The hind limbs were supported under the thigh, the knee joint and the heel while the lower leg was free. The leg was fixed to the operation table by straps over the thigh and foot. In order to avoid traumatization of the lower leg no pressure was exerted against it during the operation. After washing of the skin with spirit a 2 cm long arciform skin incision was made lateral to the knee joint. A skin flap with its base on the medial side was dissected free and folded over medially. The patellar ligament was exposed and incised longitudinally. An awl which had been ground so as to produce four sides was then inserted into the medullary cavity under the patellar ligament so as to produce a hole about 4.5 mm in diameter and slowly and carefully rotated about 1 cm into the cavity.

The contents of the medullary cavity were removed by one of the following three methods:

1 *Reaming* The narrowest reamer with a diameter of 2.52 mm was first inserted into the medullary cavity slowly and under rotation. The reaming was then repeated with successively wider reamers until a layer of cortex of an estimated thickness of $\frac{1}{4}$ mm had been removed from the middle part of the bone. The reaming was performed intermittently about a half minute of reaming being followed by a half minute interval.

2 *Suction* The contents of the cavity were sucked out through a polyethylene catheter with an inner diameter of 1.5 mm. The suction was repeated three times and between each suction an elastic metal spiral about 1 mm thick and with a curved end was inserted into the medullary cavity under rotation in order to mobilize bone marrow attached to the endosteum.

3 *Brushing* The content of the medullary cavity was mobilized by means of a bottle brush 7 mm thick and 2 cm long attached to a wire shaft. The brush was inserted into the medullary cavity as far as the distal metaphysis and then withdrawn. The brushing was repeated twice.

The skin incision was closed with silk sutures and the wound covered with Nobecutan[®].

Bone Labelling

In order to label the newly formed bone an intravenous or intraperitoneal injection of tetracycline (Dumocyclin[®] Dumex¹) was given in a dose of $\frac{1}{10}$ g/kg body weight. Dumocyclin was kindly supplied by Dumex Ltd. Denmark.

The rabbits were kept separately in ordinary rabbit cages with floors of wire netting. They were given free access to water and to food pellets with a standardized content of calories, minerals and vitamins.

Reamer Equipment for Widening of the Medullary Cavity

For reaming of the medullary cavity plain excavating burs for dental use manufactured by Hager and Meisinger, Dusseldorf, were used. Eleven different burr numbers were used with burr head diameters of 2.52–4.72 mm. The increase of the burr head diameter between each burr number was 0.1–0.3 mm. A 15–20 cm long shaft in the form of a wire spiral was constructed of piano wire. The external diameter of the wire spiral was 2.5 mm for the narrowest burs and 3.5 mm for the widest.

The burr was divided 10 mm below the head and the neck of the burr was ground down to a diameter of 1 mm. The ground burr neck was inserted into the central canal of the wire spiral to about 2 mm from the head and soldered into the canal (Fig. 1). The reamers so produced were kept standing in spirit when not in use. For reaming of the medullary cavity the reamer shaft was fixed in a sterilized chuck which was driven by a flexible drive axle covered by a sterile linen bag and this axle was coupled to an electric motor with a rotation rate of 300 r.p.m. The motor was controlled by a foot switch.

the abdomen was opened by a midline incision. The small blood vessels in the abdominal wall which had been severed at the laparotomy were left open. The aorta was exposed below the renal arteries and ligated proximally. Through an incision in the aorta a polyethylene catheter with an inner diameter of 1.1 mm was inserted distally until its tip lay immediately above the aortic bifurcation. A strong blood flow was obtained through the catheter. The catheter was connected to a drip infusion apparatus for infusion of the Indian ink solution. The infusion pressure was about 130 cm H₂O. As a rule the animals died when 200-300 ml of the solution had been infused. Towards the end of the infusion the infusion rate decreased spontaneously and gradually. After infusion of 800-1000 ml the infusion was discontinued. Both legs were then exarticulated at the hip joint. The skin was removed from the thigh and lower leg after which the limb was fixed in 10% neutralized formalin solution contained in a large vessel. After 2 days the tibia was dissected free from the skin and outer soft tissue. Fixation in formalin was then continued for a further 5 days after which the preparations were frozen to -20°C.

Macroradiography

Macroradiographs were taken of both tibias in the frontal projection.

Preparation

In the general morphological series the tibia in the deep-frozen state was divided with a saw 2.5 and 7.5 cm from the tibiotalar joint. The intermediate 5 cm of the diaphysis was used for the preparation of sections for fluorescence microscopy, microangiography and conventional histology. From each end of the diaphyseal preparation $\frac{1}{2}$ cm was sawn off and decalcified. A further $\frac{1}{2}$ cm was sawn off from each end and embedded in methyl methacrylate. The remaining 3 cm long part of the diaphysis was sawn longitudinally into one fibular and one tibial half. The fibular half was decalcified and embedded in paraffin. The tibial half was embedded in methyl methacrylate. In the other series of experiments the tibia was divided according to some different scheme as described in the relevant chapters.

The preparations intended for plastic embedding were dehydrated in absolute alcohol which was changed daily for 5 days. They were then transferred to non-polymerized methyl methacrylate in which they were kept for 4 days after which they were embedded in glass tubes in partially polymerized methyl methacrylate which was finally polymerized in a heat chamber at 30°C during a period of 3-4 days. Slices $\frac{1}{2}$ mm thick were then sawn

Fig 1 The reamer with its flexible axis is inserted through the patellar ligament which was incised longitudinally

50 mg/kg body weight. Animals studied at shorter observation times than 3 days did not undergo bone labelling. All other animals were given the labelling substance intraperitoneally 2 days before the angiographic examination. This labelling was called labelling 2. In the main experimental groups all animals were given one further labelling called labelling 1 intravenously or intraperitoneally 0-7 days after the reaming of the medullary cavity. As a rule for labelling 1 the growing animals were given tetracycline 0-1 day after the operation and the adult animals 1-4 days after the operation. The remaining animals not belonging to the main experimental groups with an observation time of >3 days underwent labelling 1 at varying times after the operation.

Microangiographic Procedure

200 ml of Pelikan Indian ink suspended in 800 ml of physiological saline was used as the infusion medium. At the end of the observation time the animal was anaesthetized with Nembutal[®] and 2 ml of heparin (5000 U/ml) was given intravenously. The animal was placed in the supine position and

Fig 2 Drawn image of the distal fluorescence section with the vascular front drawn in. The drawing is divided into 4 sectors: 1 tibial, 2 dorsal, 3 fibular, 4 ventral. Line A: The outer boundary of the outer fluorescent line resulting from labelling 2. Line B: The inner boundary of the inner fluorescent line resulting from labelling 1. Line C: The vascular front obtained from the Spalteholz preparation. Line D: The peripheral boundary of the bone removed on reaming. Line E: The inner borderline of the original cortex against the medullary cavity.

When no bone was removed on reaming, lines D and F coincide.

Each sector is divided into the following areas:

AB: Bone formed between and during labellings 1 and 2.

BC: Original cortex.

CD: Vascularized part of original cortex.

DE: Avascular part of original cortex.

EF: Part of original cortex removed on reaming.

(line A see below) lay on the fibular side of both tibial corners of the profile drawing. A line was drawn parallel with this line through the fibular boundary of the medullary cavity. The fibular corners then lay within the fibular sector. From the respective intersection points with the outer fluorescence line, lines were then drawn straight through the cortex to the medullary cavity. These lines coincided essentially with the principal direction of the intracortical vessels.

B Assessment of Vascularization

On the plastic embedded non-decalcified cross sections which had been photographed, the Indian ink filling of the intracortical vessels could only be assessed incompletely. For this purpose, thicker preparations treated according to the Spalteholz technique were required. From the plastic-embedded preparations, a further $\frac{1}{2}$ mm thick section was therefore cut.

from the methyl metacrylate-embedded specimens, parallel with the cut surface of the bone. For this purpose a bandsaw was used with a 100 μ set blade, whereby a distance of 300 μ was obtained between the preparations. The slices were ground and polished by hand with sandpaper to a thickness of 50–100 μ and then mounted in Permunt under a cover glass. Fluorescence microscopy was performed with a conventional binocular microscope with Zeiss large fluorescence equipment. Selected fluorescence preparations and Spalteholz preparations were photographed on Ektachrome High Speed 23 din for daylight, Kodachrome II or Addox kb 14.

The bone preparations intended for preparation of Spalteholz specimens and conventional histological specimens were decalcified with 5% nitric acid and embedded in paraffin. From the paraffin embedded preparations $\frac{1}{2}$ mm thick sections were sawn parallel with the cut surface of the bone. The paraffin was removed with xylol, the sections treated according to the Spalteholz technique, and studied in a binocular microscope.

In order to assess the amount of newly formed bone, the amount of bone removed on reaming and the degree of intracortical vascular damage the following methods were used.

A Division of Preparations

Colour diapositives of transverse plastic embedded cross sections were projected in a magnification apparatus and the images drawn on paper, so that the total longitudinal magnification was 30.1 times. The images from the treated side and from the control side were always projected in such a way that equivalent images were obtained (Fig. 2). On the profile drawing the outer boundary of the outer fluorescence line, the inner boundary of the inner fluorescence line and the borderline between the medullary cavity and the cortex were drawn in. On the profile drawing from the treated side the points at which the reamer had cut into the cortex were marked on the latter borderline. The central borderline for the bone which had been removed during the reaming was determined by comparison with the corresponding area from the control side as follows. The diapositive from the control side was projected on to the profile drawing from the treated side so that the corresponding endosteal line of the control side passed through the points in the drawing of the treated side at which the reamer had cut into the cortex. The intermediate endosteal borderline of the control side was then drawn on the profile drawing of the treated side.

The profile drawing was divided into four sectors: (1) tibial, (2) dorsal, (3) fibular and (4) ventral. The boundaries between the sectors were determined by drawing a line through the tibial boundary of the medullary cavity so that the intersection between this line and the outer fluorescence line

3 *Area CD* The part where the vessels were not filled with Indian ink (avascular part of original cortex)

4 *Area DE* The part which had been removed on reaming of the medullary cavity (part of original cortex removed on reaming)

The size of the different areas was usually determined planimetrically and expressed in per cent of the whole cortical area at the start of the experiment the original cortex i.e. of the area *BE* (see below)

C Special Methods of Measurement

In the following cases the position of line *A* could not be determined exactly on profile drawing of the colour diapositive of the fluorescence preparation

1 When there was no periosteal new bone formation at the second tetracycline labelling. In these cases the borderline between periosteum and underlying bone could sometimes not be identified

2 When the bone formation was very rapid at the second labelling especially on the formation of trabecular bone. The borderline between fluorescence labelled bone and later formed non labelled bone was then often diffuse and could not be determined exactly

The position of line *B* on the projected image was uncertain in the following cases

1 When labelling 1 gave weak fluorescence. The fluorescence line which then occurred could then be impossible to identify on the projected image

2 When at the first labelling the bone grew rapidly with the formation of primary osteons. In these cases the fluorescence from the maturing osteons central to the labelling line *B* could completely obscure this line

The technical error in drawing of the projected image could also be of great importance for the reliability of the recording if the distance between lines *A* and *B* on the profile drawing was very small and only amounted to about one mm

If the preparation was sawn obliquely the fluorescence lines would appear broader than they were in reality. If for example the preparation was sawn at an angle of 10° and was $50\ \mu$ thick the distance *AB* would be lengthened by $8.8\ \mu$. This would mean that the value obtained for the bone area *AB* would be approximately 0.1 too large calculated in per cent of the area *BE*. If for example area *AB* comprised 0.5% of area *BE* the value obtained for area *AB* would be 0.6% .

In order to avoid the above difficulties direct measurements were also made on fluorescence preparations in the microscope for recording of the

adjacent to the section which was used for preparing the photographed fluorescence section. The methyl metacrylate was removed with chloroform after which the section was decalcified and treated according to the Spalteholz technique. By means of a microscope and a table which could be raised or lowered, the image of this Spalteholz preparation was given the same size as and projected onto the drawn image of the corresponding fluorescence preparation. The vascular pattern in the projected image of the Spalteholz preparation comprised a summation image of the vessels in the $1\frac{1}{2}$ mm thick section. The borderline between the intracortical vessels which had filled with Indian ink and those which lacked Indian ink was called the vascular front. This line was drawn between that part of every Indian ink-filled vessel which lay nearest to the medullary cavity. In cases where no Indian ink-filled vessels were found within a distance of 3-4 mm the borderline was drawn towards the periphery until an Indian ink filled vessel was seen within this distance. No Indian ink-filled vessels were then found in the cortex central to the vascular front, but peripheral to this borderline some Haversian canals without Indian ink-filled vessels could be seen.

The distance between the plastic embedded preparation and the corresponding Spalteholz preparation was about $1\frac{1}{2}$ mm, and the profile drawing obtained thus comprised a summation image of one fluorescence preparation and one Spalteholz preparation taken about $1\frac{1}{2}$ mm from one another.

When the vascular front had been drawn, the following lines were then present on the profile drawing counting from the periphery (see Fig 2) *A* the outer boundary of the outer fluorescence line. This fluorescence line resulted from tetracycline labelling 2 which was given 2 days before the angiographic examination. *B* the inner boundary of the inner fluorescence line. This fluorescence line resulted from labelling 1. *C* the vascular front obtained from the Spalteholz preparation. *D* the peripheral boundary for the bone removed on reaming. *E* the inner borderline of the cortex against the medullary cavity and the inner boundary of the bone removed on reaming. In the unreamed areas of the cortex, lines *D* and *E* coincided. See fig 2.

The profile drawing of the cortex was thus divided into the following areas within each sector.

1 *Area AB* The part of the cortical cross section area which was labelled by the two tetracycline injections and the part between these labelling lines.

2 *Area BC* The area of original cortex in which the vessels were filled with Indian ink on angiography (vascularized part of original cortex).

3 *Area CD* The part where the vessels were not filled with Indian ink (avascular part of original cortex)

4 *Area DE* The part which had been removed on reaming of the medullary cavity (part of original cortex removed on reaming)

The size of the different areas was usually determined planimetrically and expressed in per cent of the whole cortical area at the start of the experiment the original cortex i.e. of the area *BE* (see below)

C Special Methods of Measurement

In the following cases the position of line *A* could not be determined exactly on profile drawing of the colour diapositive of the fluorescence preparation

1 When there was no periosteal new bone formation at the second tetracycline labelling. In these cases the borderline between periosteum and underlying bone could sometimes not be identified

2 When the bone formation was very rapid at the second labelling especially on the formation of trabecular bone. The borderline between fluorescence labelled bone and later formed non labelled bone was then often diffuse and could not be determined exactly

The position of line *B* on the projected image was uncertain in the following cases

1 When labelling 1 gave weak fluorescence. The fluorescence line which then occurred could then be impossible to identify on the projected image

2 When at the first labelling the bone grew rapidly with the formation of primary osteones. In these cases the fluorescence from the maturing osteones central to the labelling line *B* could completely obscure this line

The technical error in drawing of the projected image could also be of great importance for the reliability of the recording if the distance between lines *A* and *B* on the profile drawing was very small and only amounted to about one mm

If the preparation was sawn obliquely the fluorescence lines would appear broader than they were in reality. If for example the preparation was sawn at an angle of 10° and was $50\ \mu$ thick the distance *AB* would be lengthened by $8.8\ \mu$. This would mean that the value obtained for the bone area *AB* would be approximately 0.1% too large calculated in per cent of the area *BE*. If for example area *AB* comprised 0.5% of area *BE* the value obtained for area *AB* would be 0.6%.

In order to avoid the above difficulties direct measurements were also made on fluorescence preparations in the microscope for recording of the

adjacent to the section which was used for preparing the photographed fluorescence section. The methyl metacrylate was removed with chloroform after which the section was decalcified and treated according to the Spalteholz technique. By means of a microscope and a table which could be raised or lowered the image of this Spalteholz preparation was given the same size as and projected onto the drawn image of the corresponding fluorescence preparation. The vascular pattern in the projected image of the Spalteholz preparation comprised a summation image of the vessels in the $1\frac{1}{2}$ mm thick section. The borderline between the intracortical vessels which had filled with Indian ink and those which lacked Indian ink was called the vascular front. This line was drawn between that part of every Indian ink-filled vessel which lay nearest to the medullary cavity. In cases where no Indian ink-filled vessels were found within a distance of 3-4 mm the borderline was drawn towards the periphery until an Indian ink filled vessel was seen within this distance. No Indian ink-filled vessels were then found in the cortex central to the vascular front, but peripheral to this borderline some Haversian canals without Indian ink filled vessels could be seen.

The distance between the plastic-embedded preparation and the corresponding Spalteholz preparation was about $1\frac{1}{2}$ mm and the profile drawing obtained thus comprised a summation image of one fluorescence preparation and one Spalteholz preparation taken about $1\frac{1}{2}$ mm from one another.

When the vascular front had been drawn, the following lines were then present on the profile drawing counting from the periphery (see Fig 2): *A* the outer boundary of the outer fluorescence line. This fluorescence line resulted from tetracycline labelling 2 which was given 2 days before the angiographic examination. *B* the inner boundary of the inner fluorescence line. This fluorescence line resulted from labelling 1. *C* the vascular front obtained from the Spalteholz preparation. *D* the peripheral boundary for the bone removed on reaming. *E* the inner borderline of the cortex against the medullary cavity, and the inner boundary of the bone removed on reaming. In the unreamed areas of the cortex lines *D* and *E* coincided. See fig 2.

The profile drawing of the cortex was thus divided into the following areas within each sector:

1 *Area AB* The part of the cortical cross section area which was labelled by the two tetracycline injections and the part between these labelling lines.

2 *Area BC* The area of original cortex in which the vessels were filled with Indian ink on angiography (vascularized part of original cortex).

sectional area of $7.46 (\text{SE} \pm 0.64)$ was removed on reaming (In growing animals 6.6° and in adult animals 8.4°)

Tetracycline Labelling of Newly Formed Bone

Tetracycline was used for labelling of the newly formed bone since this is a simple method which in several investigations has given almost perfect correlation with microroentgen and autoradiography (Harris *et al* 1962) and also with histological studies of osteoid bands (Kelly *et al* 1965, Vanderhoeft *et al* 1962). Tetracycline forms chelates with calcium ions. When ever calcium ions are interchanged or set free i.e. during mineralization and demineralization an equilibrium reaction with tetracycline takes place (Eger *et al* 1967). Injected tetracycline becomes bound to all cartilage and bone which is undergoing mineralization (Frost *et al* 1961, Vanderhoeft *et al* 1962). The level of tetracycline in the blood is adequate to label the bone for approximately 8 hours following an intraperitoneal injection (Tapp 1966). Tetracycline given by this route can be expected to give the same good labelling as that injected intravenously (Ahlgren 1968). The diffuse tetracycline fluorescence in the tissues disappears within 2 days after the injection (Harris *et al* 1962, Frost *et al* 1961) and in order to avoid this source of error labelling 2 was given 2 days before the angiographic examination.

Labelling of Howship's lacunae which was recorded by Hulth & Olerud (1962) takes place according to Eger *et al* (1967) during the resorption phase of the bone. This labelling occurred often in the preparations of the present study. The labelling band on bone resorption can be distinguished from that on bone formation by its thinness and by the fact that in the former case the border of the bone surface is uneven. The binding of tetracycline in the calcification zone—if the animal has not been given tetracycline during the last day before death—has been described by Frost *et al* (1961) and Harris *et al* (1962) as a form of surface stain. According to Hansson (1967) this tetracycline deposition occurs mainly postvitally *inter alia* in the fixation bath. This labelling was sometimes observed in the present study as an extremely thin fluorescent band on the surface of the bone outside the fluorescent band from labelling 1 or 2 if the latter band lay at a short distance from the bone surface. Since the labelling band in the calcification zone is always very thin it can usually be identified easily.

The Bone suppressing Effect of Tetracycline

According to Eger *et al* (1967) tetracycline causes hypoplasia of dental enamel by (1) suppressing the formation of crystal nuclei (2) preventing

positions of lines *A* and *B*. The measurements were performed at a magnification of 320 times. The microscope could then be focused exactly to the upper layer of the preparation, which eliminated essentially the increase in breadth which occurred if the preparation was sawn obliquely. The exact positions of lines *A* and *B* could also be more easily established even if the labellings were weak or if irrelevant fluorescence disturbed the image.

Approximation of area *AB* was performed as follows. On the profile drawing line *A* was divided in each sector into six equal parts by means of dividers. The division points were denoted points 0, 1, 2, 3, 4, 5 and 6. The length of each sixth was recorded on the profile and denoted *a*. On the preparation the distance between lines *A* and *B*, included the width of the two fluorescent bands, was measured with an ocular micrometer at points 1, 3 and 5 and the mean value of these measurements was given as the thickness (*T*) of the newly formed bone. With the magnification used one ocular micrometer unit *U* corresponded to 3.5μ . Area *AB* was expressed in the same planimeter unit as was used in the planimetric determination of the other areas on the profile drawing of the fluorescence preparation. The values for area *AB* so obtained were expressed in per cent of area *BE*.

For approximation of area *AB* the following formula was used for each sector

$$\frac{T \cdot 3.5}{1000} \cdot 30.1 \cdot 6a \cdot \frac{10.82}{10000} \text{ units}$$

where

$\frac{T \cdot 3.5}{1000}$ = the mean value of the three thicknesses of *AB* measured in the microscope at points 1, 3 and 5, expressed in mm

a = $\frac{1}{6}$ of the length of line *A* within the sector, expressed in mm

30.1 = the longitudinal enlargement of the fluorescence profile drawing obtained as the mean value of 10 control measurements with $s.e. = \pm 0.05$

$\frac{10.82}{10000}$ = the number of planimeter units corresponding to 1 mm²

Discussion of the Methods

The flexible shaft of the reamer made it possible for the reamer to follow the S shaped tendency of the medullary cavity. In the tibial diaphysis especially in the distal part the medullary cavity is oval. The reamer thus removed bone practically solely from the ventral and dorsal sectors, while only small amounts of bone were removed in the tibial and fibular sectors.

From the area of the tibia from which the distal fluorescence section was taken 3.0–3.5 cm above the tibio talar joint a mean cortical cross

sectional area of 7.4 (± 0.64) was removed on reaming (In growing animals 6.6 and in adult animals 8.4°)

Tetracycline Labelling of Newly Formed Bone

Tetracycline was used for labelling of the newly formed bone since this is a simple method which in several investigations has given almost perfect correlation with microroentgen and autoradiography (Harris *et al* 1962) and also with histological studies of osteoid bands (Kelly *et al* 1965 Van derhoeft *et al* 1962). Tetracycline forms chelates with calcium ions. When ever calcium ions are interchanged or set free i.e. during mineralization and demineralization an equilibrium reaction with tetracycline takes place (Eger *et al* 1967). Injected tetracycline becomes bound to all cartilage and bone which is undergoing mineralization (Frost *et al* 1961 Vanderhoeft *et al* 1962). The level of tetracycline in the blood is adequate to label the bone for approximately 8 hours following an intraperitoneal injection (Tapp 1966). Tetracycline given by this route can be expected to give the same good labelling as that injected intravenously (Ahlgren 1968). The diffuse tetracycline fluorescence in the tissues disappears within 2 days after the injection (Harris *et al* 1962 Frost *et al* 1961) and in order to avoid this source of error labelling 2 was given 2 days before the angiographic examination.

Labelling of Howship's lacunae which was recorded by Hulth & Olerud (1962) takes place according to Eger *et al* (1967) during the resorption phase of the bone. This labelling occurred often in the preparations of the present study. The labelling band on bone resorption can be distinguished from that on bone formation by its thinness and by the fact that in the former case the border of the bone surface is uneven. The binding of tetracycline in the calcification zone—if the animal has not been given tetracycline during the last day before death—has been described by Frost *et al* (1961) and Harris *et al* (1962) as a form of surface stain. According to Hansson (1967) this tetracycline deposition occurs mainly postvitally *inter alia* in the fixation bath. This labelling was sometimes observed in the present study as an extremely thin fluorescent band on the surface of the bone outside the fluorescent band from labelling 1 or 2 if the latter band lay at a short distance from the bone surface. Since the labelling band in the calcification zone is always very thin it can usually be identified easily.

The Bone suppressing Effect of Tetracycline

According to Eger *et al* (1967) tetracycline causes hypoplasia of dental enamel by (1) suppressing the formation of crystal nuclei (2) preventing

positions of lines *A* and *B*. The measurements were performed at a magnification of 320 times. The microscope could then be focused exactly to the upper layer of the preparation, which eliminated essentially the increase in breadth which occurred if the preparation was sawn obliquely. The exact positions of lines *A* and *B* could also be more easily established even if the labellings were weak or if irrelevant fluorescence disturbed the image.

Approximation of area *AB* was performed as follows. On the profile drawing line *A* was divided in each sector into six equal parts by means of dividers. The division points were denoted points 0, 1, 2, 3, 4, 5 and 6. The length of each sixth was recorded on the profile and denoted *a*. On the preparation the distance between lines *A* and *B*, including the width of the two fluorescent bands, was measured with an ocular micrometer at points 1, 3 and 5 and the mean value of these measurements was given as the thickness (*T*) of the newly formed bone. With the magnification used one ocular micrometer unit, *U*, corresponded to 3.5μ . Area *AB* was expressed in the same planimeter unit as was used in the planimetric determination of the other areas on the profile drawing of the fluorescence preparation. The values for area *AB* so obtained were expressed in per cent of area *BE*.

For approximation of area *AB* the following formula was used for each sector

$$\frac{T \cdot 3.5}{1000} \cdot 30.1 \cdot 6a \cdot \frac{10.82}{10000} \text{ units}$$

where

$\frac{T \cdot 3.5}{1000}$ = the mean value of the three thicknesses of *AB* measured in the microscope at points 1, 3 and 5 expressed in mm

a = $\frac{1}{6}$ of the length of line *A* within the sector expressed in mm

30.1 = the longitudinal enlargement of the fluorescence profile drawing obtained as the mean value of 10 control measurements with $SE = \pm 0.05$

$\frac{10.82}{10000}$ = the number of planimeter units corresponding to 1 mm

Discussion of the Methods

The flexible shaft of the reamer made it possible for the reamer to follow the S-shaped tendency of the medullary cavity. In the tibial diaphysis especially in the distal part the medullary cavity is oval. The reamer thus removed bone practically solely from the ventral and dorsal sectors while only small amounts of bone were removed in the tibial and fibular sectors.

From the area of the tibia from which the distal fluorescence section was taken 3.0–3.5 cm above the tibio-talar joint a mean cortical cross-

water while about 200 ml of Indian ink was infused. The animal usually died after infusion of this amount of Indian ink. The flow through the small abdominal wall vessels was then profuse. In two animals the bleeding vessels in the abdominal wall were ligated. The venous pressure then rose during the infusion to about 40 cm of water. Subsequently bleeding occurred from the omentum among other places after which the venous pressure gradually decreased. No venous pressure exceeding 23 cm of water was recorded during the infusion when the abdominal wall vessels were left open.

The profuse blood flow obtained from the catheter which had been inserted into the distal part of the aorta showed that the lower extremities are supplied with blood even if the aorta is ligated. During the infusion the Indian ink was therefore mixed in successively higher concentrations with the blood which perfused the legs right up to the time when the animal died. This method of perfusion has been found to give good visualization of the entire vascular system of the diaphysis including intracortical capillaries and sinusoids in the medullary cavity. The vessels leading from the periosteum into the cortex are very narrow throughout however and there is a risk that these vessels may be obliterated by the Indian ink with the result that the filling of vessels in the underlying cortex will be incomplete. In order to counteract the deposition of fibrin on the ink particles the animals were heparinized. Studies of longitudinal sections of Spalteholz preparations have also shown that within a height difference of a few mm large differences in Indian ink filling of the intracortical vessels seldom occur. The vascular pattern in the Spalteholz preparation taken about $\frac{1}{2}$ mm from the fluorescence preparation can therefore be considered to reflect satisfactorily the Indian ink filling in the cortex of the fluorescence preparation.

In the Spalteholz preparations which were prepared from paraffin-embedded sections the soft tissue structures and cortex were well preserved. These preparations make possible detailed studies of soft tissue vessels and intracortical vessels. The Spalteholz preparations prepared from the primary plastic embedded bone swelled when the methyl metacrylate was dissolved with chloroform as a result of which the soft tissues around the bone and in the medullary cavity were destroyed. Bone preparations often buckle but as a rule the cortex remains otherwise intact. These preparations are therefore only suitable for evaluation of the intracortical vascular filling and not for evaluation of the vessels of soft tissues.

Errors of Calculation

The error on calculating the area *CD* i.e. that area of the cortical cross section in which the vessels did not fill with Indian ink at angiography

the growth of crystallites, and (3) blocking the conversion by hydrolysis of primary octacalcium orthophosphate into apatite

Saxen (1966) found in *in vitro* studies that tetracycline in a concentration of 500 $\mu\text{g/ml}$ completely inhibited the development of the calcified zone in bone rudiment. The effect was irreversible after it had been present for 5 days. Hansson (1967) found that tetracycline in a dose of 25 mg/kg body weight disturbed both the endochondral calcification process and the resorption of the cells of the degenerated cartilage.

Tetracycline in the dose used here approximately 50 mg/kg can thus probably have a negative influence on the mineralization and growth of bone tissue. Whether tetracycline also interferes with resorption of bone tissue is unknown. The effect is greater at higher tissue concentrations (Hansson 1967).

In this material, on evaluation of the amount of newly formed bone the treated side was compared with the control side. The rate of periosteal bone formation was at least at first, higher on the treated than on the control side. A negative effect of tetracycline on bone mineralization and bone formation should therefore tend to reduce the difference between the treated tibia and the control tibia and thus not result in overestimation of the differences obtained.

Absence of Bone Labelling

Six of the animals nos 46, 50, 92, 85, 77 and 56 showed a complete absence of fluorescent bone after labelling 2. All of these animals were given tetracycline in an intraperitoneal injection at the second labelling. The reason for the lack of fluorescence is not clear but it might be that the tetracycline was injected into the large intestine and was therefore not absorbed. These animals could not be evaluated completely on fluorescence microscopy. Labelling 1 resulted in fluorescence of bone in all cases.

Angiographic Technique

At the angiographic procedure the cut vessels in the abdominal wall were left open in order to counteract an increase of the central venous pressure and thereby reduce the risk of extravasation of Indian ink which easily occurs especially in the medullary cavity. In order to obtain an idea of what pressure occurred in the venous system the central venous pressure was recorded in seven animals on a graded tube during infusion of Indian ink. A polyethylene catheter was introduced into the vena cava via the renal vein. At the start of the infusion practically no measurable venous pressure was recorded. When the vessels in the abdominal wall were left open after the laparotomy the venous pressure rose slowly to 15–20 cm

water while about 200 ml of Indian ink was infused. The animal usually died after infusion of this amount of Indian ink. The flow through the small abdominal wall vessels was then profuse. In two animals the bleeding vessels in the abdominal wall were ligated. The venous pressure then rose during the infusion to about 40 cm of water. Subsequently bleeding occurred from the omentum among other places after which the venous pressure gradually decreased. No venous pressure exceeding 23 cm of water was recorded during the infusion when the abdominal wall vessels were left open.

The profuse blood flow obtained from the catheter which had been inserted into the distal part of the aorta showed that the lower extremities are supplied with blood even if the aorta is ligated. During the infusion the Indian ink was therefore mixed in successively higher concentrations with the blood which perfused the legs right up to the time when the animal died. This method of perfusion has been found to give good visualization of the entire vascular system of the diaphysis including intracortical capillaries and sinusoids in the medullary cavity. The vessels leading from the periosteum into the cortex are very narrow throughout however and there is a risk that these vessels may be obliterated by the Indian ink with the result that the filling of vessels in the underlying cortex will be incomplete. In order to counteract the deposition of fibrin on the ink particles the animals were heparinized. Studies of longitudinal sections of Spalteholz preparations have also shown that within a height difference of a few mm large differences in Indian ink filling of the intracortical vessels seldom occur. The vascular pattern in the Spalteholz preparation taken about $\frac{1}{2}$ mm from the fluorescence preparation can therefore be considered to reflect satisfactorily the Indian ink filling in the cortex of the fluorescence preparation.

In the Spalteholz preparations which were prepared from paraffin embedded sections the soft tissue structures and cortex were well preserved. These preparations make possible detailed studies of soft tissue vessels and intracortical vessels. The Spalteholz preparations prepared from the primary plastic embedded bone swelled when the methyl metacrylate was dissolved with chloroform as a result of which the soft tissues around the bone and in the medullary cavity were destroyed. Bone preparations often buckle but as a rule the cortex remains otherwise intact. These preparations are therefore only suitable for evaluation of the intracortical vascular filling and not for evaluation of the vessels of soft tissues.

Errors of Calculation

The error on calculating the area *CD* i.e. that area of the cortical cross section in which the vessels did not fill with Indian ink at angiography

Fig 3 Relationship between the size of the area AB within each sector measured planimetrically on a drawn image (see p 29) (abscissa) and approximated according to the formula given on p 32 (ordinate). All sectors with approximated AB values greater than 0.2 U are included. Of sectors with AB values below 0.2 U a representative number are included. The figure shows that there is good correlation between the two methods of recording at approximated AB values greater than 0.2 U but a low correlation at lower AB values.

was determined by drawing the same preparation, from animal 125, on five different occasions. The mean value for area CD amounted to 50.5% with $SE = \pm 0.32$. The reliability of the recording was considered to be adequate.

On measurement of area AB the primary aim was to use planimetry as was used in the measurement of the other areas on the profile drawing. It was found, however, that on measurement of small area the error in the drawing could be very large, often several hundred per cent. Area AB was therefore always approximated with the previously given formula (p 32). The error in this approximation was studied by correlating the results obtained on approximation of the area with the formula and the results obtained on planimetry (see Fig 3). With large AB values the correlation between the two methods was very high, but with small AB values, where approximation should give the most reliable value, the correlation was low. Approximation with the formula should thus be a better method in these cases than planimetry.

Measurement of the thickness of AB in the microscope was performed at three points within each sector. The change of the thickness within one sector usually takes place continuously, and three measurements within each sector were considered to be representative of the sector.

In order to determine the size of the error of measurement for the thick

Table 2 Mean value and standard deviation for 10 measurements of the thickness of AB in each of 5 sectors with trabecular bone primary osteones and circumferential lamellae

	Trabecular bone					Primary osteones					Circumferential lamellae				
Mean	125	45	45	45	281	125	281	244	240	237	51	58	123	270	9
SD	32.5	11.7	4	72.6	123.4	95.4	7.8	32.6	7.1	22.8	38.6	23.1	8.8	3.2	11.1
SE	1.52	5.40	2.70	5.04	9.04	1.14	1.54	1.05	0.95	3.33	0.55	0.47	0.47	1.10	1

ness AB 10 separate measurements of the thickness were performed within each of five sectors with trabecular bone (t) primary osteones (o) and circumferential lamellae (l) (Table 2) For each series of 10 observations the mean value and standard deviation were calculated The size of the error of measurement for each individual bone structure was calculated with the aid of the standard deviations of the five individual series according to the formula

$$\sqrt{\frac{\sum SD^2}{5}} = SD_i$$

The error of measurement (SD_i) of the individual observation was ± 5.4 U for trabecular bone ± 1.83 U for osteones and ± 0.75 U for circumferential lamellae These errors comprise a reasonable estimate of the error to which the individual observation value for the respective bone structure is subject On measurement of the thickness AB the mean value of several determinations within one sector or within several different sectors was calculated In these cases the error of the mean will be smaller than that of the individual observation

The variation caused by the systematic error of measurement can be correlated to the biological variation by forming the quotient

$$\frac{\sum SD^2}{5} : SD^2 m_i$$

$SD : m$ is the variance for the mean value of the five observation series for trabecular bone primary osteones and circumferential lamellae respectively and in this material is mainly an expression of the biological variation With the above formula the quotient for trabecular bone was 0.021 for osteones 0.017 and for circumferential lamellae 0.008 This is a rough measure of the relative importance of the error of measurement and the quotient is so low that the error of measurement can be regarded as of secondary importance in relation to the biological variations

The area of the bone removed on reaming was approximated from the profile drawing for the control side. The error arising in this approximation was assessed by recording the natural difference between the right and left sides within the ventral and dorsal sectors in five control animals. The endosteal line within the middle $\frac{1}{6}$ of the sectors from the profile image from the left tibia was drawn over the corresponding line on the profile image from the right tibia and the area between these lines was calculated and expressed in per cent of area *BE*. The mean difference in the ventral sector was -0.4% , *s.d.* ± 6.6 and in the dorsal sector 0.5% , *s.d.* ± 2.7 .

Pressure Variations in the Medullary Cavity on Reaming and Brushing out of the Cavity in the Rabbit

Wehner (1968) has shown that on closed reaming and nailing of tibial fractures in man pressure variations from -100 mm Hg to $+120$ mm Hg can occur in the medullary cavity (See p. 6). Larsen (1938) considers that an intramedullary pressure increase can give rise to necrosis of the cortex and Nick *et al.* (1965) claim that the rise in pressure to about 75 mm Hg which can be observed in a fracture haematoma may be an important factor in fracture healing.

Recording of the intramedullary pressure variations which occur in the medullary cavity on reaming and brushing by the method used in the present study was considered to be motivated here as an aid to establishing the cause of the intracortical vascular damage.

Material

Two adult rabbits were used.

Method

The anaesthesia and operative technique were as described on pages 25.

The intramedullary pressure was recorded in the distal tibial metaphysis which was exposed ventrally about $1\frac{1}{2}$ cm above the tibiotalar joint. A hole 3.3 mm in diameter was drilled here through the ventral cortex. The hole was plugged with a plastic plug through which a polyethylene catheter with an outer diameter of 1.5 mm and with a wall thickness of 0.2 mm was inserted. The catheter was filled with heparin solution and was connected to a pressure transducer (Elema-Schonander EMT 490A) the nominal range of recording of which is $0-300$ mm Hg. The pressure was recorded by means of a direct writing ink recorder (Minicograf 42B Elema-Schonander Solna, Sweden). The apparatus was calibrated between each recording and correction for drift was made.

Pressure recording was performed during the following stages of the operative procedure.

Fig 4

Fig 5

Fig 4 Recording of intramedullary pressure when the medullary cavity is opened with an awl under the ligamentum patellae. At (a) the medullary cavity is opened carefully with the awl which is then held still in the hole. At (b) the hole is widened carefully and at (c) the awl is forced down into the medullary cavity and rotated at the same time. Pressure variations considerably exceeding 100 mm Hg can be seen.

Fig 5 Recording of intramedullary pressure on insertion of a reamer into the medullary cavity. At (a) the rapidly inserted rotating reamer comes into contact with endosteal bone. At (b) the reamer is withdrawn a few cm and is then again forced into the medullary cavity. (c) When the reamer is moved up and down in narrow parts of the medullary cavity considerable pressure variations can occur.

- 1 When the medullary cavity was opened with an awl below the patellar ligament.
- 2 When the reamer was inserted in the medullary cavity
- 3 On reaming of the endosteal cortex in the medullary cavity
- 4 When the reamer was removed from the medullary cavity
- 5 When a bottle brush was inserted into and withdrawn from the medullary cavity

Results

The spontaneous pressure in the medullary cavity was found to be about 30 mm Hg.

Recording at stage 1 When the medullary cavity was opened with an awl a fall in pressure was first noted. When the awl was held still the pressure lay at a level of about 30 mm Hg. On moving the awl again a further rise in pressure of the order of 25 mm Hg was obtained. When the awl was forced down into the medullary cavity and rotated at the same time a pressure increase to considerably over 100 mm Hg occurred. On movement of the awl considerable negative pressure was also observed (Fig 4).

Recording at stage 2 When the reamer was introduced under rotation into the medullary cavity a pressure rise was recorded. When it was inserted slowly very small pressure increases occurred but when it was inserted quickly pressure increases to above 300 mm Hg were noted. Large reamer heads appeared to cause greater pressure increases than smaller reamer heads under otherwise identical conditions (Fig 5).

Recording at stage 3 During the reaming a moderate and varying pressure rise of fairly long duration can be seen but rapid pressure variations of the

Fig 6

Fig 7

Fig 6 Recording of intramedullary pressure on reaming of the medullary cavity. A moderate pressure increase of long duration and rapid pressure variations can be seen.

Fig 7 Recording of intramedullary pressure on brushing in the medullary cavity. Very large pressure variations can be seen.

order of 200 mm Hg also occurred. The rapid pressure variations were introduced by a negative phase and followed by a positive phase, the negative phase being the greater (Fig 6).

Recording at stage 4 When the reamer was withdrawn from the medullary cavity the pressure in the cavity decreased to below zero. The order of magnitude of the decrease was dependent upon the rate at which the reamer was withdrawn. Considerable negative pressures were recorded when the reamer was withdrawn rapidly (Fig 5).

Recording at stage 5 When a bottle brush was inserted into the medullary cavity a pressure increase to considerably over 300 mm Hg, more than twice the range of the transducer, was recorded. When the brush was withdrawn there was a considerable decrease in pressure (Fig 7).

Discussion

When the medullary cavity is opened carefully with a rotating awl, which is only inserted about 1 cm into the medullary cavity, and the reamer is then introduced slowly and under rotation, the pressure in the distal part of the medullary cavity does not increase to more than about 60 mm Hg, which is twice the normal medullary cavity pressure. It seems that under these circumstances the reamer head is able, by a pump action, to gradually transport backwards parts of the contents of the medullary cavity past the reamer head and thereby help to prevent the occurrence of a large pressure increase. On reaming in endosteal bone, large pressure variations can occur and variations up to 200 mm Hg were recorded. These pressures are of the same order as those reported by Wehner (1968). The pressure variations give rise to varying pressures and a suction action in the Haver

sian canals of the diaphysis. It is probable that on occurrence of these pressure variations material is easily squeezed into the Haversian canals from the medullary cavity. The pressure variations in the medullary cavity can probably also cause the vessels in the Haversian canals which are very fragile to tear.

Brushing of the medullary canal can give rise to even greater intramedullary pressure variations than reaming.

Conclusions

Intramedullary pressure variations are probably an important cause of intracortical vascular damage on reaming of the medullary cavity. The pressure variations can be reduced if the medullary cavity is opened carefully and if the reamer is moved up and down slowly in the medullary cavity.

Determination of Temperature Increase on Reaming of the Medullary Cavity in the Rabbit

One possible reason for the occurrence of vascular trauma in the cortex on reaming of the medullary cavity may be that the reamer by friction heat can produce thermal damage. Baar (1968) found that the function of the enzyme systems in human red blood cells was not affected negatively on heating if the temperature was kept below 42°C. Lieber (1946) claimed that pain was induced from dentine if the temperature exceeded 55°C. According to Hudoch *et al* (1939) irreversible changes occur in cell protoplasm at temperatures of 43–44°C.

In order to determine whether friction heat could give rise to thermal damage in the present material the temperature increase was recorded on reaming of the medullary cavity in the rabbit tibia.

Material

Two rabbit tibias were used immediately after death of the animals.

Method

The temperature was measured with a Thermocouple Applicator Type H 1 coupled to a Lab Thermocouple thermometer Type TE 3 with a measurement range of 0–50°C (Electrolab Copenhagen). The Applicator Type H 1 measures with a thin measuring wire and has a setting time of 1–2 sec. On recording, a constant value was first obtained followed by a slow reduction. The constant value has been given as the measurement value obtained.

A water bath was heated to 38°C. The thermoelement was placed in a stand 15 cm from the water bath and shielded from the bath. In order to record the fall

Fig 6

Fig 7

Fig 6 Recording of intramedullary pressure on reaming of the medullary cavity A moderate pressure increase of long duration and rapid pressure variations can be seen

Fig 7 Recording of intramedullary pressure on brushing in the medullary cavity Very large pressure variations can be seen

order of 200 mm Hg also occurred. The rapid pressure variations were introduced by a negative phase and followed by a positive phase, the negative phase being the greater (Fig 6).

Recording at stage 4 When the reamer was withdrawn from the medullary cavity the pressure in the cavity decreased to below zero. The order of magnitude of the decrease was dependent upon the rate at which the reamer was withdrawn. Considerable negative pressures were recorded when the reamer was withdrawn rapidly (Fig 5).

Recording at stage 5 When a bottle brush was inserted into the medullary cavity a pressure increase to considerably over 300 mm Hg, more than twice the range of the transducer, was recorded. When the brush was withdrawn there was a considerable decrease in pressure (Fig 7).

Discussion

When the medullary cavity is opened carefully with a rotating awl which is only inserted about 1 cm into the medullary cavity and the reamer is then introduced slowly and under rotation the pressure in the distal part of the medullary cavity does not increase to more than about 60 mm Hg which is twice the normal medullary cavity pressure. It seems that under these circumstances the reamer head is able by a pump action to gradually transport backwards parts of the contents of the medullary cavity past the reamer head and thereby help to prevent the occurrence of a large pressure increase. On reaming in endosteal bone large pressure variations can occur and variations up to 200 mm Hg were recorded. These pressures are of the same order as those reported by Wehner (1968). The pressure variations give rise to varying pressures and a suction action in the Haver-

(4) The pressure applied to the instrument Stronger pressures against the instrument give greater heat development

Brånemark (1958) observed a temperature increase of $10-12^{\circ}\text{C}$ on grinding of the cortex in rabbit fibulas at 300 r p m when no cooling fluids were used Vaughn & Peyton (1951) on drilling in dental enamel with drills 1.4-1.7 mm in diameter at 1300 r p m found a temperature increase of about 30°C Since the heat development in enamel has been estimated to be three times as great as in dentine (Peyton 1952) the heat development in dentine under these experimental conditions would have been about 10°C According to Brånemark (1958) cortical bone is most closely comparable with dentine

In the present series of experiments on living rabbits reamers of relatively wide calibre were used The diameters of the reamer heads ranged from 3.02-4.92 mm the diameter increasing by up to 0.3 mm for each reamer number The reaming of the medullary cavity was performed successively the cavity being widened by a maximum of 0.3 mm with each reamer used and reaming of bone took place only by the most peripheral part of the reamer head Under these circumstances the heat development should be considerably less than if reamers of corresponding size were used in the reaming of solid bone in which case the whole of the anterior surface of the reamer would be in contact with the bone The rate of rotation used —300 r p m—is also relatively low The temperature increase observed in these experiments thus corresponds well with previous experimental results

During operations in the medullary cavity in living animals the reamer is cooled by blood circulating in the cortex and by the blood which flows into the medullary cavity from the cortex With the method used for assessing the temperature increase on reaming the rise in temperature on reaming in living bone is probably not underestimated

Conclusions

Although the experimental conditions differ somewhat from those in reaming of the medullary cavity in living animals it is reasonable to assume that about the same temperature increases max $3-4^{\circ}\text{C}$ are produced locally in the medullary cavity in both cases

On intermittent reaming with no appreciable pressure against the reamer the temperature increase occurring should not damage the bone tissue

in temperature on the reamer head when this was transferred from the water bath to the thermoelement the head and about 3 mm of the shaft of reamer no 16 were held in the water bath for 1 min. The reamer was then moved at a constant rate into contact with the measuring electrode. This was done by inserting the measuring wire into one of the grooves of the reamer so that as large a contact surface as possible was created between the reamer and the measuring electrode. The recording was repeated five times. The same experiment was repeated six times with the water bath heated to 45–48°C.

Freshly removed rabbit tibiae were divided transversally in the middle of the diaphysis. The distal part of the bone was fixed in the water bath which had been heated to 38°C so that the osteotomy surface lay a few mm above the surface of the water. The head of reamer no 16 which is 3.9 mm in diameter was heated in the water bath for 1 min. The medullary cavity of the tibia was then reamed for $\frac{1}{2}$ min using slight pressure against the bone and with a rotation rate of 300 rpm after which the reamer was moved towards the thermoelement at the same rate as in the preparatory experiments and the temperature on the reamer head was recorded. Five reaming experiments were performed. The same reamer equipment was used as in the experimental series.

Results

The mean reduction in temperature when the reamer was heated in the water bath and then transferred to the measuring electrode was 5°C (range 4–8°C) when the water bath temperature was 38°C. At a water bath temperature of 45–48°C the mean temperature reduction was 6°C with a range of 5–6°C.

On reaming of the medullary cavity after preheating of the reamer the maximal increase in temperature was 3°C with a range from –2 to +3°C when correction was made for the temperature fall of 5°C noted when the reamer was transferred from the water bath to the thermoelement and 4°C when correction was made for a temperature fall of 6°C.

Discussion

In these experiments the reamer lost heat via radiation, fluid evaporation and conduction through the neck of the reamer to its shaft. An attempt was made to keep these factors as constant and comparable as possible in the preparatory and main experiments.

In odontology the development of heat on the drilling of teeth has attracted great interest. Peyton (1952) found that the heat development on drilling is dependent upon (1) The material in which the drilling is performed. Drilling in enamel causes heat development three times as great as drilling in dentine. (2) The type of instrument used. Small drill heads give less heat development than large. (3) The number of revolutions of the drill. A low rate of rotation gives less heat development than higher rates.

(4) The pressure applied to the instrument Stronger pressures against the instrument give greater heat development

Brånemark (1958) observed a temperature increase of $10-12^{\circ}\text{C}$ on grinding of the cortex in rabbit fibulas at 300 r.p.m. when no cooling fluids were used Vaughn & Peyton (1951) on drilling in dental enamel with drills 1.4-1.7 mm in diameter at 1300 r.p.m. found a temperature increase of about 30°C Since the heat development in enamel has been estimated to be three times as great as in dentine (Peyton 1952) the heat development in dentine under these experimental conditions would have been about 10°C According to Brånemark (1958) cortical bone is most closely comparable with dentine

In the present series of experiments on living rabbits reamers of relatively wide calibre were used The diameters of the reamer heads ranged from 3.02-4.92 mm the diameter increasing by up to 0.3 mm for each reamer number The reaming of the medullary cavity was performed successively the cavity being widened by a maximum of 0.3 mm with each reamer used and reaming of bone took place only by the most peripheral part of the reamer head Under these circumstances the heat development should be considerably less than if reamers of corresponding size were used in the reaming of solid bone in which case the whole of the anterior surface of the reamer would be in contact with the bone The rate of rotation used—300 r.p.m.—is also relatively low The temperature increase observed in these experiments thus corresponds well with previous experimental results

During operations in the medullary cavity in living animals the reamer is cooled by blood circulating in the cortex and by the blood which flows into the medullary cavity from the cortex With the method used for assessing the temperature increase on reaming the rise in temperature on reaming in living bone is probably not underestimated

Conclusions

Although the experimental conditions differ somewhat from those in reaming of the medullary cavity in living animals it is reasonable to assume that about the same temperature increases max. $3-4^{\circ}\text{C}$ are produced locally in the medullary cavity in both cases

On intermittent reaming with no appreciable pressure against the reamer the temperature increase occurring should not damage the bone tissue

Effect of Reaming of the Medullary Cavity in the Rabbit Tibia

GENERAL REACTION OF THE ANIMALS

The animals bore weight on the treated leg on the day after the operation. In no case was there any clinically manifest infection in the operation area and neither did any wound-rupture occur.

MACRORADIOGRAPHIC STUDIES

On specimens observed at 0-2 weeks, thinning of the cortex on the treated side was often observed in the middle part of the tibia. At an observation time of 2 weeks and later some animals showed a periosteal deposition of relatively low contrast density which was sometimes thicker than the original cortex. The periosteal deposition occurred in some cases along the greater part of the cortex but in others it was localized to a limited area often located in the proximal fibular part of the diaphysis dorsal to the insertion of the fibula on the tibia. In one preparation observed at 5 weeks (13) (Fig. 8) a zone of low density was observed at that location between the original cortex and the periosteal callus tissue. At the same time in some animals a patchy area of increased contrast density was seen in the medullary cavity. In some animals studied at an observation time of more than 2 weeks there was considerably increased density in the medullary cavity and at the same time the borderline between the cortex and medullary cavity was indistinct.

FLUORESCENCE MICROSCOPIC STUDIES

Normal Transverse Growth in the Diaphysis of the Long Bone in the Rabbit

The normal transverse growth of the long bone takes place in the diaphysis by the formation of lamellar bone on the periosteal surface at the same time as bone is resorbed from the endosteal surface. The lamellar bone can consist of primary osteones or of circumferential lamellae. When the rabbit is 3-4 months old its periosteum in the distal part of the diaphysis in the ventral sector often forms primary osteones so rapidly that several layers of osteones mature simultaneously. In the dorsal sector the formation of la

Fig 8 X ray picture of rabbit tibia 5 weeks after reaming of the medullary cavity. A zone of low density between the old cortex and a newly formed thin cortex on the dorsal side of the bone indicates a cavity in the callus. Increased contrast density is seen in some areas in the medullary cavity (The same animal as in *Fig 20*.)

mellar bone is as a rule alternated with bone resorption during this time. In the tibial and fibular sectors lamellar bone is usually formed. No woven bone was observed in this material during normal periosteal bone growth. The rate of periosteal bone formation decreases during growth. The previously formed primary osteones are superimposed during growth by circumferential lamellae.

On the endosteal surface resorption alternates with the formation of lamellar bone.

Parts of the cortex are reconstructed successively. According to Owen *et al* (1955) this takes place especially in those areas of the cortex where in their opinion there are residual fragments of calcified epiphyseal cartilage. On tetracycline labelling these areas of reconstruction appear on cross section as fluorescent ring shaped structures and on longitudinal section so-called cutter heads (Schenk 1963) can be observed during the formation of secondary osteones (Color pl 1 a b 3 a).

Fluorescence Microscopic Observations after Reaming of the Medullary Cavity

The material for this study comprised animals in Table 1. In the subperiosteal layer the morphology and reconstruction of the newly formed

bone were especially studied, and in the cortex the initial absence of bone formation and the rebuilding of vascularized and avascular cortex. In the medullary cavity a study was made of the primary absence of fluorescence on endosteal bone, new bone formation, bone resorption and restoration of the normal medullary structures.

For the evaluations, each section was compared with the corresponding section from the control side in cases where only one tibia was treated (61/86 animals). The animal numbers are referred to table 1. D indicates the distal transverse section and P the proximal transverse section.

Observation time 0-2 days

These animals were not given tetracycline. Two of the animals (27 and 28) showed subperiosteal bleeding at the insertion of the fibula on the tibia.

Observation time 3 days

Labelling 1 was given 1 day postoperatively.

Periosteum The periosteum on the treated side had usually formed bone and osteoid tissue of the same structure as on the control side. In some cases however woven bone had formed on the treated side while on the control side lamellar bone was observed.

In the formation of woven bone beams or spicules of osteoid were first formed which later become calcified between two periosteal blood vessels. Two closely adjacent beams were then united by bone, which formed a bridge over vessels lying nearby.

The development of the periosteal bone formation could be followed by giving tetracycline at different time points after the operation and studying the location in the bone tissue at which the tetracycline was deposited. When tetracycline was given at the time of the operation the fluorescent band always had the same appearance and thickness on the treated side as on the control side. The structure of the bone and osteoid outside the fluorescent band showed however that woven bone could have been formed later than 8 hours postoperatively.

When tetracycline in growing animals was given on the day after the operation, homogeneously fluorescent beams or spicules of woven bone up to 100 μ high were found between two blood vessels during the formation of trabecular bone (Fig. 9) (125 D). In some preparations (125 P, 124 P) incomplete fluorescent bridges between adjacent beams could be seen peripheral to the blood vessels. When primary osteones were formed within an area where such osteones had been formed before the operation the postoperatively formed primary osteones were often built of lamellar bone alone. Beam shaped structures of woven bone sometimes occurred instead between

Fig 9 Distal fluorescence cross section of ventral cortex observation time 3 days Growing animal 125 labelled on day 1 Fluorescent spicules of newly formed subperiosteal bone are seen and between these radiating blood vessels The visible part of the cortex is well vascularized from periosteal vessels

blood vessels in the same way as in the formation of trabecular bone. This latter type of primary osteone developed even when circumferential lamellae had been formed before the operation or when preoperatively the periosteum had been inactive.

In the adult animals many sectors showed no active bone formation but when bone formation did occur almost only circumferential lamellae were observed at 3 days.

In a preparation from the growing animal 125 P a haemorrhage about 1 mm thick which had not taken up Indian ink was seen on the fibular side cranial to the insertion of the fibula on the tibia. In the angle between the raised periosteum over this haemorrhage and the cortex newly formed trabecular bone was observed (Fig 10). The smooth bone surface under the centre of the haemorrhage completely lacked fluorescence. Minor haemorrhages in the corresponding region were seen in a further three growing animals (3, 114, 124) and two adults (54, 110).

Cortex In the cortex signs of absence of bone formation activity were observed on the treated side. Thus fluorescence was lacking in many areas adjacent to the medullary cavity and on the endosteal surface where fluorescent bone was present on the control side (Color pl. 1). This absence of

bone were especially studied and in the cortex the initial absence of bone formation and the rebuilding of vascularized and avascular cortex. In the medullary cavity a study was made of the primary absence of fluorescence on endosteal bone, new bone formation, bone resorption and restoration of the normal medullary structures.

For the evaluations each section was compared with the corresponding section from the control side in cases where only one tibia was treated (61/86 animals). The animal numbers are referred to table 1. D indicates the distal transverse section and P the proximal transverse section.

Observation time 0-2 days

These animals were not given tetracycline. Two of the animals (27 and 28) showed subperiosteal bleeding at the insertion of the fibula on the tibia.

Observation time 3 days

Labelling 1 was given 1 day postoperatively.

Periosteum The periosteum on the treated side had usually formed bone and osteoid tissue of the same structure as on the control side. In some cases however woven bone had formed on the treated side while on the control side lamellar bone was observed.

In the formation of woven bone beams or spicules of osteoid were first formed, which later become calcified between two periosteal blood vessels. Two closely adjacent beams were then united by bone, which formed a bridge over vessels lying nearby.

The development of the periosteal bone formation could be followed by giving tetracycline at different time points after the operation and studying the location in the bone tissue at which the tetracycline was deposited. When tetracycline was given at the time of the operation the fluorescent band always had the same appearance and thickness on the treated side as on the control side. The structure of the bone and osteoid outside the fluorescent band showed however that woven bone could have been formed later than 8 hours postoperatively.

When tetracycline in growing animals was given on the day after the operation homogeneously fluorescent beams or spicules of woven bone up to 100 μ high were found between two blood vessels during the formation of trabecular bone (Fig. 9) (125 D). In some preparations (125 P, 124 P) incomplete fluorescent bridges between adjacent beams could be seen peripheral to the blood vessels. When primary osteones were formed within an area where such osteones had been formed before the operation the postoperatively formed primary osteones were often built of lamellar bone alone. Beam shaped structures of woven bone sometimes occurred instead between

Fig 11 Proximal fluorescence cross section of fibular cortex observation time 3 days Growing animal 124 labelled on day 1 Indian ink filled blood vessels are traversing the cortex to the medullary cavity Extravasation of Indian ink is seen in the medullary cavity close to the endosteum Bone fragment in the medullary cavity adjacent to the Indian ink extravasation are fluorescent which is a sign that tetracycline has diffused out into the medullary cavity blood clot here 1 day after the operation

the first and second labellings were often confluent In some of the youngest animals however two separate fluorescent bands were seen In these cases the outer band was broader than the inner (e.g. 64) This indicates that the rate of bone formation was higher 5 days than 1 day after the operation assuming that the absorption conditions of the tetracycline were the same on the two labelling occasions Since tetracycline was given as an intraperitoneal injection both at labelling 1 and 2 these conditions should have been identical

Primary osteones with woven and trabecular bone which had been labelled 2 days postoperatively showed in growing animals broader fluorescent beams between the blood vessels than those which were labelled on the day after the operation (Fig 12) Complete bridges were often observed over the blood vessels (65-97) From the labelling given 3 days after the operation (83) both broad beams between the blood vessels and bridges over them were fluorescent in both growing and adult animals A suggestion of fluorescence of beams leading to osteones of the next generation was

Fig 10 Proximal fluorescence cross section of fibular cortex observation time 3 days Growing animal 125 labelling on day 1 postoperatively There is a subperiosteal haematoma dorsally and between the tibia and fibula The bone surface is inactive in the central part under the haematoma but around this part even on the fibula trabecular bone is formed

bone formation was most clearly observed in the young animals in which normally there is active reconstruction of the inner part of the cortex In the cortical areas in which no bone formation activity was observed Indian ink filling of the intracortical blood vessels was also lacking

Medullary cavity In one preparation (124 P) an almost sector shaped area in the medullary cavity containing fluorescent bone fragment was found (Fig 11) These bone fragments had been detached from the endosteal cortex on reaming Passing to this area from the periosteum through the cortex was an Indian ink filled blood vessel and extravasation of Indian ink was observed in the medullary cavity blood clot between the fluorescent bone fragments and the endosteal surface In the remaining parts of the preparation the medullary cavity was filled with a clot containing non fluorescent bone fragments

Observation time 1 week

Labelling 1 was given 1 day and labelling 2 5 days postoperatively

Periosteum When lamellar bone had formed the fluorescent bands from

Fig 13 Distal fluorescence cross section of ventral cortex observation time 4 weeks
 Growing animal 7 labelled on days 7 and 26 postoperatively. In the subperiosteally formed primary osteones ring shaped structures of lamellar bone show fluorescence after labelling 1. The osteones are almost closed at labelling 2 and are covered by circumferential lamellae. In the inner part of the cortex reconstruction is taking place. The bone trabeculae in the medullary cavity surrounded by wide Indian ink filled vessels are undergoing extensive resorption but deposition of bone is also observed.

bular bone and primary osteones was observed at the insertion of the fibula on the tibia without any signs of resorption or reconstruction in this callus tissue. In no animal was any major subperiosteal bleeding observed.

Cortex In one animal (95) there was a tendency to widening of some bone canals in the subperiosteal part of the original cortex. In the inner parts of the cortex an absence of fluorescence was observed in the same way as described for an observation time of 3 days.

Medullary cavity The medullary cavity contained a blood clot containing bone fragments. In several preparations newly formed blood vessels had invaded the medullary cavity. Around these vessels a wreath of small fluorescent old bone fragments was seen but no newly formed bone was observed in the medullary cavity.

Observation time 2 weeks

Labelling 1 was given 1 to 7 days and labelling 2 12 days postoperatively.

Periosteum In one growing animal in which lamellar bone was formed during labelling on days 1 and 12 after the operation the fluorescent band

Fig 12 Proximal fluorescence cross section of the fibular part of the cortex observation time 8 weeks Growing animal 65 labelled 2 and 54 days postoperatively There are trabeculae of woven bone and bridges over vessels fluorescence labelled 2 days postoperatively Labelling 54 days postoperatively shows that the osteones were closed at that time The osteones are covered with circumferential lamellae after partial superficial resorption Reconstruction is taking place in the inner half of the cortex The bone trabeculae in the visible part of the medullary cavity are resorbed and replaced by almost normal marrow

also frequently observed When tetracycline had been given 4 days postoperatively bridges to osteones of the second generation and beams to third generation osteones were sometimes fluorescent When tetracycline had been given 7 days after the operation the beams of woven bone between blood vessels to primary osteones of the first generation were no longer fluorescent (Fig 13) In these preparations fluorescence was observed instead in a ring shaped layer of lamellar bone around the blood vessels (7)

The woven bone which had been labelled 1 and 5 days after the operation showed however massive almost homogeneous fluorescence of all the newly formed bone (105)

In the adult animals the formation of circumferential lamellae predominated In two animals (121 112) the formation of primary osteones was also seen These showed a somewhat lower degree of development than the primary osteones in the young animals

In several growing animals (e.g. 104 105) very active formation of tra

Fig 14 Proximal fluorescence cross section of fibular cortex observation time 2 weeks Adult animal 86 labelled on days 2 and 12 postoperatively Active periosteal callus formation with no appreciable resorption A canal in the subperiosteal original cortex is filled with an Indian ink filled vessel and is increasing in calibre which is evident from its width and rough surface

cortex nearer to the medullary cavity many of the bone canals were considerably wider than in the outer area of the cortex These canals ran through the cortex in the direction of the medullary cavity Their foremost part was often widened into a pear shape and comprised so called cutter heads (Fig 15) The bone surface was rough and partially labelled with a thin fluorescent layer of the type which can be seen on bone undergoing resorption Further peripherally on the walls of the bone canals new bone had been laid down whereby a secondary osteone had been formed In growing animals large resorption cavities occurred not infrequently in the inner part of the cortex In these cavities some preparations showed new formation of bone on the surface facing the medullary cavity In adult animals similar changes were seen to those in the growing animals The resorption canals were narrower throughout however and no large resorption cavities were found in the cortex

Medullary cavity Blood vessels had invaded the medullary cavity in many of the growing animals and in some of the adults In no preparation was newly formed bone observed in the medullary cavity

after labelling 1 was narrower than that after labelling 2. In another growing animal which was labelled on days 7 and 12, the fluorescent band after labelling 1 was broader than that after labelling 2. The rate of bone formation thus appeared in the one case to be higher 12 days than 1 day postoperatively, and in the other case higher 7 days than 12 days postoperatively (59, 6). The tetracycline was given in the same way at both labellings, in the respective animals.

The newly formed, primary osteones and the trabecular bone had matured further. From labelling 2, in first generation osteones ring shaped lamellar bone was fluorescent around blood vessels (Fig 14), and in second and third generation primary osteones and in trabecular bone beams of woven bone fluoresced between blood vessels. The perivascular soft tissue had decreased correspondingly. In many sectors resorption was in progress from the surface of the newly formed bone. In the ventral and sometimes also the dorsal sector the bone formation often seemed to be greatest over that part of the cortex which had been most thinned by the reaming (Color pl 1 b Fig 18). Often in these cases primary osteones were formed in the area which was most thinned and circumferential lamellae at the sides of this area.

In the region around the insertion of the fibula on the tibia no subperiosteal haemorrhage was observed in any of the preparations. In many growing animals a large area of callus consisting of trabecular bone was found instead in this area. Also in many adult animals trabecular bone was observed at this location but to a smaller extent than in the growing animals. In the central parts of this callus an extensive resorption of the newly formed bone beams was in progress (Fig 16). In the peripheral parts of the callus new often lamellar bone was deposited on the bone bridges. In this way the bone tissue became condensed peripherally and transformed successively to cortical bone (6). A similar reconstruction of callus was also observed in other areas of the diaphysis but only seemed to take place where a large amount of woven bone had been formed primarily and not when lamellar bone had been formed.

Cortex In the outer parts of the cortex signs of reconstruction of the bone were observed in both growing and adult animals. The bone canals for many of the blood vessels which passed from the periosteum into the cortex were thus wider on the treated side than on the control side in all growing animals and in two of the five adults. The walls of the bone canals were often uneven due to the presence of Howship's lacunae which indicated bone resorption (Fig 14). In growing animals large resorption cavities occurred on the surface of the original cortex but only in areas over which trabecular bone had been deposited (45) (Color pl 2 a). In revascularized parts of the

Fig 14 Proximal fluorescence cross section of fibular cortex observation time 2 weeks Adult animal 86 labelled on days 2 and 12 postoperatively Active periosteal callus formation with no appreciable resorption. A canal in the subperiosteal original cortex is filled with an Indian ink filled vessel and is increasing in calibre which is evident from its width and rough surface

cortex nearer to the medullary cavity many of the bone canals were considerably wider than in the outer area of the cortex. These canals ran through the cortex in the direction of the medullary cavity. Their foremost part was often widened into a pear shape and comprised so called cutter heads (Fig 15). The bone surface was rough and partially labelled with a thin fluorescent layer of the type which can be seen on bone undergoing reorption. Further peripherally on the walls of the bone canals new bone had been laid down whereby a secondary osteone had been formed. In growing animals large resorption cavities occurred not infrequently in the inner part of the cortex. In these cavities some preparations showed new formation of bone on the surface facing the medullary cavity. In adult animals similar changes were seen to those in the growing animals. The resorption canals were narrower throughout however and no large resorption cavities were found in the cortex.

Medullary cavity. Blood vessels had invaded the medullary cavity in many of the growing animals and in some of the adults. In no preparation was newly formed bone observed in the medullary cavity.

Fig 15 Distal fluorescence cross section of tibial part of cortex observation time 2 weeks Growing animal 108 labelled on days 1 and 12 postoperatively Revascularization of the cortex is taking place by means of cutter heads in the direction towards the medullary cavity (to the right) The cortex is being resorbed around the leading narrow vessel loop and new bone is being deposited on the wall of the eroded bone canal further peripherally close to fairly wide blood vessels massively filled with Indian ink

Observation time 3 weeks

Periosteum The blood vessel canals in the primary osteones formed post operatively had decreased further in width Active formation of lamellar bone was in progress on the walls of the bone canals around the blood vessels Extensive resorption was observed on the surface of the newly formed bone

Cortex In the cortex many of the bone canals had widened further and on the walls in many of the resorption cavities in the inner parts of the cortex fluorescent new bone was observed

Medullary cavity In several preparations from growing animals newly formed blood vessels and also a sparse amount of newly formed fluorescent woven bone was seen in the medullary cavity adjacent to the endosteum

Observation time 4 weeks

Labelling 1 was given 0-3 days and labelling 2 26 days postoperatively

Periosteum In the first generation primary osteones formed after the

Fig 16 Proximal fluorescence cross section of fibular cortex observation time 2 weeks Growing animal 6 labelled on days 7 and 12 postoperative y A large amount of trabecular bone has been formed in the dorsal angle between the fibula and tibia The central part of the newly formed bone is undergoing resorption while the peripheral part is being condensed to cortical bone

operation the bone canals showed practically the same width as in the original cortex (Fig 13) The bone formation on the walls of these bone canals had almost ceased (7-97) The first formed primary osteons were in many cases superimposed by circumferential lamellae

In the area around the insertion of the fibula on the tibia a large amount of trabecular bone appeared to have formed primarily after the operation in two young animals At this observation time a hood of newly formed condensed periosteal bone was found in this area (Fig 17) Under this hood there was a cavity in the callus tissue filled with a tissue which on the fluorescence preparation resembled normal medullary tissue The cavity lay on the section right inside the callus tissue It was separated from the original cortex by a thin layer of bone which was partially undergoing resorption from inside the cavity On the largest part of the peripheral wall of the cavity active bone formation was observed (51-52) Only in preparations from one animal (97) was formation of woven bone under the periosteum in progress for the rest, only lamellar bone

Cortex In the young animals several bone canals in the outer part of the cortex were widened and filled with wide Indian ink filled blood vessels

Fig 17 Proximal fluorescence cross section of fibular cortex observation time 4 weeks Growing animal 52 labelled on days 1 and 26 postoperatively There is a cavity in the periosteal callus tissue of trabecular bone The cavity is separated from the surface of the original cortex by a thin layer of bone which is largely undergoing resorption from the cavity on the peripheral surface of which bone formation is taking place

On the walls of these canals active bone reconstruction, with both resorption and bone formation was in progress Many bone canals in the outer part of the cortex did not seem to be undergoing any reconstruction however but showed the same appearance as on the control side In the inner parts of the cortex some of the growing animals showed large resorption cavities (Fig 19) which were partly lined with new fluorescent bone on the surface facing the medullary cavity while the opposite surface usually exhibited resorption In other parts of the inner cortex small cavities were seen often with bone formation around the entire circumference (Fig 13)

In the adult animals qualitatively the same reconstruction process was observed in the cortex as in the growing animals but the widened vascular canals were regularly considerably narrower and no large resorption cavities were found in the cortex

Medullary cavity In five of the seven growing animals and two of the five adults fluorescent bone trabeculae built of woven bone were found in the medullary cavity In some of the young animals and in one of the adults the central parts of the trabeculae were not fluorescent (Figs 13 18) This was observed especially in the trabeculae lying nearest to the endosteum

Fig 18 Distal fluorescence cross section observation time 4 weeks Growing animal 7 labelled on days 7 and 76 Almost completed periosteal new bone formation Extensive superficial resorption in the dorsal sector (below) Ventrally primary osteones were first formed and ventro-fibularly (above right) trabecular bone on which circumferential lamellae were deposited Reconstruction of the inner cortex is taking place especially in the fibular sector (right) In the centre of the medullary cavity there is a sparsely vascularized area with no newly formed bone trabeculae and peripheral to this area newly formed bone trabeculae with active bone formation are seen In the surrounding areas there are relatively few Indian ink filled vessels Adjacent to the endosteal cortex especially in the fibular and tibial areas bone trabeculae which are surrounded by wide vessels massively filled with Indian ink have been largely resorbed

The centre of these trabeculae had thus become mineralized earlier than 2 days before labelling 2 was given The trabeculae in the middle of the medullary cavity were often fluorescent on all surfaces but in some cases some surfaces lacked fluorescence often surfaces facing the periphery The nonfluorescent surface was then often uneven due to the presence of Howship's lacunae In three of the growing and three of the adult animals newly formed blood vessels of wide calibre usually with thin walls were observed in the medullary cavity adjacent to the endosteum

Observation time 5-6 weeks

Periosteum In one animal a large cavity was found in callus tissue in the area around the insertion of the fibula on the tibia (13) (Fig 20) From this cavity resorption of the underlying cortex was in progress

Fig 17 Proximal fluorescence cross section of fibular cortex observation time 4 weeks Growing animal 52 labelled on days 1 and 26 postoperatively There is a cavity in the periosteal callus tissue of trabecular bone The cavity is separated from the surface of the original cortex by a thin layer of bone which is largely undergoing resorption from the cavity on the peripheral surface of which bone formation is taking place

On the walls of these canals active bone reconstruction with both resorption and bone formation was in progress Many bone canals in the outer part of the cortex did not seem to be undergoing any reconstruction however but showed the same appearance as on the control side In the inner parts of the cortex some of the growing animals showed large resorption cavities (Fig 19) which were partly lined with new fluorescent bone on the surface facing the medullary cavity while the opposite surface usually exhibited resorption In other parts of the inner cortex small cavities were seen often with bone formation around the entire circumference (Fig 13)

In the adult animals qualitatively the same reconstruction process was observed in the cortex as in the growing animals but the widened vascular canals were regularly considerably narrower and no large resorption cavities were found in the cortex

Medullary cavity In five of the seven growing animals and two of the five adults fluorescent bone trabeculae built of woven bone were found in the medullary cavity In some of the young animals and in one of the adults the central parts of the trabeculae were not fluorescent (Figs 13 18) This was observed especially in the trabeculae lying nearest to the endosteum

Fig 20 Proximal fluorescence cross section of fibular cortex observation time 5 weeks Growing animal 13 labelled on days 26 and 33 There is a cavity in the periosteal callus tissue of trabecular bone From the cavity which is filled with almost normal marrow tissue erosion is taking place of the underlying original cortex which in the centre under the cavity is avascular The same animal as in Fig 8

a fairly large cavity in the callus in the dorsal region (92) This cavity had a deeper location than in animals with shorter observation times (Fig 21) More than half of the cavity lay within the original cortex The surface of the cavity facing the medullary cavity showed a suggestion of fluorescence and on the other surface resorption of original cortex was in progress

Cortex In the growing animals the resorption processes in the cortex seemed to be less pronounced than at an observation time of 4 weeks and new bone formation predominated On the walls of most of the resorption canals and resorption cavities bone formation was observed In the inner parts of the cortex in growing animals large cavities were seen with only sporadic bone formation on the wall facing the medullary cavity In adult animals both resorption and new formation of bone were in progress on the walls of the resorption canals

Medullary cavity In all animals both growing and adult newly formed bone was found at some place in the medullary cavity In adult animals however the bone formation was often very sparse In the medullary cavity

Fig 19 Longitudinal fluorescence section observation time 4 weeks Growing animal 97 labelled on days 2 and 26 Some of the bone canals in the outer part of the cortex are widened and filled with rather wide vessels In the inner parts of the cortex large resorption cavities which are partly lined with new fluorescent bone can be seen

Observation time 8 weeks

Labelling 1 was given 0-4 days and labelling 2 54 days postoperatively

Periosteum The periosteum was inactive or had formed circumferential lamellae when labelling 2 was given The primary osteones which had formed previously in the postoperative course had usually become covered with a layer of circumferential lamellae (Fig 12) In some cases this had taken place after resorption of the peripheral parts of the woven bone which were fluorescent after the first labelling (65)

In the area of the insertion of the fibula on the tibia one animal showed

Fig 20 Proximal fluorescence cross section of fibular cortex observation time 5 weeks Growing animal 13 labelled on days 26 and 33 There is a cavity in the periosteal callus tissue of trabecular bone From the cavity which is filled with almost normal marrow tissue erosion is taking place of the underlying original cortex which in the centre under the cavity is avascular The same animal as in Fig 8

a fairly large cavity in the callus in the dorsal region (92) This cavity had a deeper location than in animals with shorter observation times (Fig 21) More than half of the cavity lay within the original cortex The surface of the cavity facing the medullary cavity showed a suggestion of fluorescence and on the other surface resorption of original cortex was in progress

Cortex In the growing animals the resorption processes in the cortex seemed to be less pronounced than at an observation time of 4 weeks and new bone formation predominated On the walls of most of the resorption canals and resorption cavities bone formation was observed In the inner parts of the cortex in growing animals large cavities were seen with only sporadic bone formation on the wall facing the medullary cavity In adult animals both resorption and new formation of bone were in progress on the walls of the resorption canals

Medullary cavity In all animals both growing and adult, newly formed bone was found at some place in the medullary cavity In adult animals however the bone formation was often very sparse In the medullary cavity

Fig 21 Proximal fluorescence cross section of fibular cortex observation time 8 weeks Growing animal 92 labelled on days 1 and 54 Condensed periosteal callus tissue which is undergoing resorption from the surface Between the callus tissue and the original cortex partly located in the original cortex there is a cavity whose central wall is undergoing resorption

in these animals large areas which had not become revascularized were seen. In other areas there was revascularization by sparsely situated blood vessels without formation of new bone around the vessels. In the growing animals resorption of bone predominated over new bone formation. Many of the trabeculae observed at the border between the richly vascularized and the central sparsely vascularized areas lacked fluorescence even on the surface facing the centre. The peripheral parts of the medullary cavity completely lacked trabeculae in many preparations. In these areas the trabeculae had been resorbed and replaced by bone marrow which seemed on the fluorescence section to have a normal structure. This bone marrow contained wide blood vessels usually veins. On the endosteal surface especially within the reamed area a layer of newly formed lamellar bone was often found.

Observation time 12 weeks

Labelling 1 was given 1-4 days and labelling 2 92 days postoperatively. The group comprised only adult animals.

Periosteum The fluorescence microscopic picture resembled that at an observation time of 8 weeks.

Cortex In the outer parts of the cortex occasional blood vessel canals which were considerably widened were found. On their walls bone formation was observed in some cases but as a rule there was no bone formation activity. In the inner parts of the cortex resorption cavities were found the walls of which showed inactivity or bone formation but in fairly large areas of the cortex there were still no signs of reconstruction.

Medullary cavity All the adult animals showed active bone formation in the medullary cavity but resorption of the trabeculae predominated in the peripheral areas of the medullary cavity. Vessels of wide calibre usually veins but in some preparations also arteries were found in the medullary cavity. The medullary cavity also contained areas with restored fat marrow of normal appearance in four of the five animals.

Discussion

On reaming of the medullary cavity the medullary blood vessels in the diaphysis of the bone are completely destroyed at the same time as bone is removed from the endosteal surface of the cortex. Reactive changes occur in the periosteum, cortex and medullary cavity.

Reaction of Periosteum

As in many previous investigations the periosteum in this study reacted with increased bone formation. The newly formed bone was of two morphological types: lamellar bone and woven bone.

Lamellar bone which can comprise circumferential lamellae or primary osteons is formed on normal periosteal growth in rabbits of the ages studied here and the formation of this bone could therefore be regarded as resumed or accelerated normal bone formation. Frost (1963) pointed out that this bone when completely developed has maximum resistance to the physical loads on the skeleton. This agrees with the present findings which showed that the central parts of the newly formed lamellar bone were not reconstructed during the period of maturation but appeared to have acquired their final properties at the initial stage.

The causal mechanism for the formation of lamellar bone under the periosteum could not be elucidated by this material. According to Frost (1963) the formation of lamellar bone is influenced by growth hormones, thyroid hormones and space polarizing factors. In the present study it was observed that the subperiosteal blood vessels were dilated during the time in which the periosteal bone formation was increased and during the subsequent phase when the bone resorption was potentiated. The primary vascular dilatation may have been due to stasis in the blood vessels. This can

lead to local anoxia and acidosis, which according to Richany *et al* (1965) and Johnson (1966) can induce subperiosteal bone formation. According to Trueta (1963) dying or hypoxic osteocytes and endothelial cells influence the blood vessels, either by their action or by their inhibition, via vascular stimulating factors. He considers that the bone formation can occur as a result of the vascular reaction.

The formation of woven bone, which can consist either of primary osteones or trabecular bone, results initially in a much more rapid increase in the thickness of the bone than the formation of lamellar bone, and when trabecular bone is formed the cortical thickness can increase twofold within the course of about 2 weeks. In the normal growth of rabbits of the ages studied here, woven bone appears never to develop subperiosteally and its presence can be considered to be pathological, so-called callus formation. The formation of trabecular bone means that large amounts of woven bone have developed. In this series trabecular bone was formed especially frequently within the area around the insertion of the fibula on the tibia. In this area preparations studied at short observation times often showed subperiosteal haemorrhages which seemed to become resorbed within the course of about 1 week. In preparations studied at longer observation times an abundance of woven bone which had probably been induced by such a haemorrhage was often observed at this site (see also p. 118). The central parts of the trabecular bone were often reconstructed by resorption of the bone trabeculae and their replacement by normal medullary tissue whereby a cavity occurred in the callus tissue. The callus tissue outside the cavity was reconstructed to cortical bone by the deposition of lamellar bone on the trabeculae around the blood vessels. The callus cavity appeared to be formed at least partly inside the callus tissue and subsequently seemed to move in the direction of the medullary cavity by the deposition of bone on its peripheral wall simultaneous with resorption of its central wall. The original cortex under the cavity was probably necrotic which may have been the reason that the callus cavity moved centrally. Zucman *et al* (1968) demonstrated that a subperiosteal haemorrhage occurring after reaming of the medullary cavity consisted partly of squeezed out marrow fat which they found gave rise to abundant periosteal bone formation in which cavities could occur. The woven bone thus seems to be a pathological bone formation which is often rebuilt during the process of maturation in order to adapt to the physiological demands placed on the extremity. Frost (1963) considers that the formation of woven bone is governed by local stimulating factors and not by growth hormones, thyroid hormones or space polarizing factors. Neither is the structure of the collagen fibres adapted to the physical load on the skeleton according to Frost (1963). In the present material woven

bone was formed during the first 2-4 weeks after the operation but subsequently only lamellar bone was formed subperiosteally Charnley (1968) has pointed out that woven bone is a provisional bone which is resorbed when it becomes covered by lamellar bone In the woven bone the calcium crystals are less closely packed The bone is therefore permeable to tetracycline which then stains the entire bone tissue (Eger & Kammerer 1967)

On the surface of the newly formed periosteal bone alternating resorption and deposition of bone takes place after an observation time of about 2 weeks The newly formed woven bone is then covered with lamellar bone often when the surface of the woven bone has first been resorbed This alternation between superficial resorption and deposition of bone is according to Schenk (1967) the natural process of adaptation of the periosteum to different functional demands on the bone

Cartilage formation under the periosteum was not observed in any of the preparations of the present study This is in agreement with the findings of Bast *et al* (1925) and Richany *et al* (1965) They found cartilage formation from the periosteum only when the latter had been opened and never under intact periosteum

Reaction of Cortex

After reaming of the medullary cavity different areas of the cortex reacted in different ways depending among other things upon whether or not the blood circulation in the area remained undisturbed Growing and adult animals also reacted somewhat differently

Reconstruction of vascularized cortex

In those parts of the cortex where the circulation remained after the intramedullary reaming many of the intracortical bone canals began to increase in width during the first 1-2 weeks after the operation At an observation time of 4 weeks several of the widened canals had begun to decrease again in width by the deposition of bone on their walls Other canals continued to become wider on the other hand The increased circulation through the outer part of the cortex to its inner part and to the medullary cavity appeared in this way to be concentrated to a smaller and smaller number of blood vessels while the remaining vessels gradually became of decreased importance

Reconstruction of avascular cortex

The avascular areas of the cortex were revascularized from areas supplied with blood partly by means of cutter heads Schenk & Willenegger (1963)

lead to local anoxia and acidosis, which according to Richany *et al* (1965) and Johnson (1966) can induce subperiosteal bone formation. According to Trueta (1963) dying or hypoxic osteocytes and endothelial cells influence the blood vessels either by their action or by their inhibition via vascular stimulating factors. He considers that the bone formation can occur as a result of the vascular reaction.

The formation of woven bone, which can consist either of primary osteones or trabecular bone, results initially in a much more rapid increase in the thickness of the bone than the formation of lamellar bone, and when trabecular bone is formed the cortical thickness can increase twofold within the course of about 2 weeks. In the normal growth of rabbits of the ages studied here woven bone appears never to develop subperiosteally and its presence can be considered to be pathological so called callus formation. The formation of trabecular bone means that large amounts of woven bone have developed. In this series trabecular bone was formed especially frequently within the area around the insertion of the fibula on the tibia. In this area preparations studied at short observation times often showed subperiosteal haemorrhages which seemed to become resorbed within the course of about 1 week. In preparations studied at longer observation times an abundance of woven bone which had probably been induced by such a haemorrhage was often observed at this site (see also p 118). The central parts of the trabecular bone were often reconstructed by resorption of the bone trabeculae and their replacement by normal medullary tissue, whereby a cavity occurred in the callus tissue. The callus tissue outside the cavity was reconstructed to cortical bone by the deposition of lamellar bone on the trabeculae around the blood vessels. The callus cavity appeared to be formed at least partly inside the callus tissue and subsequently seemed to move in the direction of the medullary cavity by the deposition of bone on its peripheral wall simultaneous with resorption of its central wall. The original cortex under the cavity was probably necrotic which may have been the reason that the callus cavity moved centrally. Zucman *et al* (1968) demonstrated that a subperiosteal haemorrhage occurring after reaming of the medullary cavity consisted partly of squeezed out marrow fat which they found gave rise to abundant periosteal bone formation in which cavities could occur. The woven bone thus seems to be a pathological bone formation which is often rebuilt during the process of maturation in order to adapt to the physiological demands placed on the extremity. Frost (1963) considers that the formation of woven bone is governed by local stimulating factors and not by growth hormones, thyroid hormones or space polarizing factors. Neither is the structure of the collagen fibres adapted to the physical load on the skeleton according to Frost (1963). In the present material woven

In the peripheral part of the medullary cavity in the growing animals of the present study at an observation time of 4 weeks resorption of the bone trabeculae facing the periphery of the bone often took place while bone formation still proceeded on the surface facing the parts of the medullary cavity which had not yet become revascularized. At the same time new trabeculae were formed more centrally in the medullary cavity. At an observation time of 8-12 weeks the trabeculae in the peripheral parts of the medullary cavity in the growing animals had often become completely resorbed and had been replaced by richly vascular medullary tissue. The bone formation had then often partially ceased even on the trabeculae which lay in the centre of the medullary cavity on the border of areas which had not yet become vascularized or which were sparsely revascularized. Brane mark (1964) observed incipient resorption of the bone trabeculae after an observation time of 3 weeks and restored marrow tissue after 4 weeks. Richany *et al* (1965) found that the marrow regeneration was largely accomplished 25 weeks after medullary removal.

In the present material the adult animals showed considerably less bone formation in the medullary cavity than the growing animals. Often at an observation time of 12 weeks large areas of the medullary cavity were still not revascularized. In no preparation had the bone formation in the medullary cavity ceased 12 weeks after the operation.

MICROANGIOGRAPHIC STUDIES

Normal Angiographic Pattern on Control Side

On Indian ink angiography with the method used here the entire vascular bed including intracortical capillaries and medullary cavity sinusoids was filled with the dye. In the different vascular systems the vessels showed different degrees of Indian ink filling. As a rule the periosteal vessels were massively homogeneously filled with the dye but the Indian ink columns in the vessels were sometimes interrupted by small unfilled or partially filled areas. In the diaphyseal cortex parts of the capillaries were massively filled or lined with Indian ink. Between these well filled parts short stretches of capillary which completely lacked contrast medium were seen. Arterioles from the medullary cavity were as a rule massively filled and could often be followed to the middle of the diaphyseal cortex. The cortex adjacent to the medullary cavity also showed however wide blood vessels in which the Indian ink lined the walls without filling the lumen. These vessels were often found to open in funnel-shaped fashion into the intramedullary sinusoids. The blood vessels in the subperiosteal bone were usually wider in the growing animals than in the adults.

described these cutter heads in fracture healing in the dog; while Geiser (1963) claimed that they do not occur in the rabbit. In the present study, cutter heads were found to drill relatively narrow canals in the bone in an oblique direction towards the medullary cavity. In addition to this form of revascularization of the cortex, resorption cavities were formed in some cases in association with broom-like vascular reactions. In some growing animals very large cavities were formed. There was a tendency for new bone to be formed on the peripheral surface of the cavity while at the same time resorption took place from its central surface. In this way the cavity moved in the direction of the medullary cavity with increasing observation times. An invasion of blood vessels and reconstruction of avascular bone was evident at an observation time of 2 weeks. In growing animals the bone resorption in avascular cortex appeared to be most pronounced at an observation time of about 4 weeks, while the new bone formation seemed to be most active at about 8 weeks. The rebuilding in the cortex thus took place when the periosteal bone formation activity had decreased. This time course corresponds well with the findings of Andersson (1965) in the dog and of Richany *et al* (1965) in adult cats. The small cavities in growing and adult animals appeared as a rule to close up completely. This process took a long time, however, and at an observation time of 12 weeks many small cavities with active bone formation on the walls were observed. Large cavities in the inner part of the cortex seem to have a tendency not to close completely. In the present material at an observation time of 8 weeks, cavities were found in the inner part of the cortex with no signs of either resorption or new bone formation on their walls. Richany *et al* found large resorption cavities filled with normal bone marrow at an observation time of 4 weeks.

Richany *et al* studied the development in adult cats over a long period and found that reconstruction in the cortex was essentially completed after 5 $\frac{1}{2}$ months. Trueta & Cavadias (1955) found that in adult rabbits necrotic areas were still to be seen in the cortex 8 months after disturbance of the endosteal circulation.

Reaction of Medullary Cavity

Regeneration of the structures in the medullary cavity after scraping away of the bone marrow has been studied in detail histologically by Branemark (1964) and Richany *et al* (1965). The results obtained for the growing animals in the present study agree essentially with the findings of these authors. Tetracycline labelling makes it possible to follow the formation and resorption of the bone trabeculae in the medullary cavity with greater reliability than do histological methods, however.

seen in some places. In preparations observed at 24 hours (61) the periosteal blood vessels were wider on the treated than on the control side.

Cortex At an observation time of less than 24 hours the filling of the intracortical capillaries was often difficult to evaluate since the Indian ink filled parts of one capillary were surrounded by long unfilled areas especially in the middle and inner part of the cortex. At an observation time of 24 hours these unfilled areas had decreased greatly in number and length. The vascular front (see p. 30) could then be determined with more reliability.

Under the subperiosteal haemorrhages the cortex usually showed no Indian ink filling of the blood vessels.

Medullary cavity In all animals occasional blood vessels from the periosteum were seen to penetrate the entire cortex to the medullary cavity. In the medullary cavity in front of the Indian ink filled vessel a minor extravasation of the dye was usually observed.

Observation time 3 days

Periosteum It was a regular finding that the periosteal vessels were massively filled with Indian ink. In four of the five young animals (3, 114, 124, 125) and two of the five adults (54, 110) there were subperiosteal haemorrhages localized to the area of the insertion of the fibula on the tibia (Fig. 10). In no case was the haematoma infused with Indian ink. In all young animals the periosteal blood vessels were wider and often more tortuous on the treated side than on the control side. The same change was observed but much less pronounced in adult animals.

Cortex From the periosteum Indian ink filled blood vessels penetrated into the cortex. A tendency to a funnel shaped widening of these vessels nearest to the periosteum was noted on the treated side in all growing animals but was not observed in adult animals. The dilatation of the blood vessels in the bone canals appeared to have taken place without the bone canals becoming wider at this time. Under the subperiosteal haemorrhages the cortex showed a considerable lack of Indian ink filling of the blood vessels. The filling of the intracortical vessels varied. In the subperiosteal bone the blood vessels were often massively filled while those further inside the cortex often showed only grains of Indian ink along the walls. In two of the five young animals (3, 124) and one of the five adults (55) blood vessels filled with Indian ink were seen to run from the periosteum through the cortex to the medullary cavity.

Medullary cavity In no preparation were any blood vessels filled with Indian ink found in the medullary cavity. A minor extravasation of Indian ink was often observed just in front of the Indian ink filled blood vessels.

In the medullary cavity both homogeneously filled, relatively narrow blood vessels, namely those which were seen to pass through half of the cortex and which were considered to be arterioles, and sinusoids the walls of which were lined with grains of Indian ink were found. Small areas of medullary cavity sinusoids were completely empty of the dye. The central vein of the medullary cavity was, as a rule lined with grains of Indian ink.

The calibre of the periosteal blood vessels and their number were highly dependent upon the bone formation activity of the periosteum. On formation of primary osteons, relatively wide, somewhat tortuous blood vessels were seen to cross each other in several layers. On formation of circumferential lamellar bone the blood vessels were narrow and straight throughout and the vascular layer thinner. On completion of bone formation only occasional narrow vessels were seen in the subperiosteal layer.

In the growing animals the blood vessels in the subperiosteal bone were usually relatively wide in calibre and in some cases two vessels were found in the same bone canal. The bone canals in the middle part of the cortex usually contained only one blood vessel. At this location two vessels in the same canal were only observed following so called cutter heads in the formation of secondary osteons (Color pl. 3 a). In the growing animals the bone canals around the blood vessels were often considerably wider than the enclosed vessel, but in the adults the bone canal was only very slightly wider than the blood vessel. In the subendosteal bone two blood vessels were sometimes found in the same bone canal. In these cases one of the vessels was often wide and its walls lined with grains of Indian ink while the other was narrow and massively filled with the dye. The former vessel was considered to be a venule and the latter an arteriole.

Microangiographic Pattern after Reaming of the Medullary Cavity

The material for this study comprised the animals in Table 1 with the exception of 81 on which angiography was not performed.

The periosteal vascular pattern varied with the local growth situation of the periosteum. Corresponding areas on the treated and control sides always had to be compared therefore before the effect of intra medullary reaming on the periosteal blood vessels could be evaluated.

Observation time 0-2 days

Periosteum In all preparations the periosteal blood vessels were massively filled with Indian ink. Two of the nine animals (27-28) showed subperiosteal haemorrhages in the area of the insertion of the fibula on the tibia. In the subperiosteal haemorrhages a small leakage of Indian ink was

Cortex Blood vessels passing from the periosteum into the cortex widened in funnel shape fashion in three of the six young animals (64 66 95) and in one of the three adult animals (121). A tendency to the same reaction was observed in one further young animal (105). The intracortical blood vessels were more massively filled with Indian ink than those observed at 3 days but otherwise had the same appearance.

Medullary cavity Newly formed blood vessels had invaded the medullary cavity in all young animals and in two of the three adults (121 44). In all cases the vessels had only invaded from endosteal surface which had not been damaged by the reamer. The vessels which first invaded the medullary cavity comprised a three-dimensional irregularly shaped network of mutually anastomosing vessels with pronounced calibre variation. In cross section the blood vessels were often polygonal with a diameter of between 2 and 30 μ .

Observation time 2 weeks

Periosteum The vascular reactions in the periosteum were similar to those at an observation time of 1 week but as a rule more pronounced (Color pl 2 a). Apart from the previously described vascular reactions wide round blood vessels of equal calibre lined with grains of Indian ink were now seen in the deeper parts of the periosteal callus tissue in the areas where the long periosteal vessels perpendicular to the bone surface had formed previously. The course of these vessels was essentially parallel to the bone surface. This vascular reaction occurred on bone resorption when cavities were formed in trabecular bone. In all of the young animals and in three of the five adults the blood vessels passing from the periosteum into the cortex were dilated.

Cortex In the outer part of the cortex many but not all of the intracortical vessels were dilated. In deeper parts of the cortex there were two forms of vascular reaction which could occur within the same section. The most common reaction which was observed in all growing and adult animals comprised loops of blood vessels forming a ball with a diameter of about 20-35 μ . In some cases several vessels could be seen leading to these loops. This accumulation of blood vessels appeared to occur at the border between cortical areas in which the vessels had filled with Indian ink on angiography and areas with no Indian ink filling. It comprised the vascular component of a cutter head which revascularized the cortex (Color pl 3 a). The other vascular reaction consisted of large broom-shaped bundles of blood vessels inside the cortex or between the original cortex and periosteal newly formed bone (Color pl 2 a). At the base of the vascular broom a narrow massively filled blood vessel and several wider vessels

Fig 22 Distal Spalteholz preparation from ventro-tibial part of cortex observation time 3 days Growing animal 124 Practically all blood vessels in the cortex nearest to the medullary cavity are filled with Indian ink From several vessels in the non reamed part of the cortex extravasation of Indian ink into the medullary cavity blood clot is seen

which opened into the medullary cavity (Figs 11 22) as in preparations at shorter observation times

Observation time 1 week

Periosteum In all animals with the exception of one adult (126) periosteal blood vessels were observed which showed changes compared with corresponding areas on the control side The vascular reaction varied In the least pronounced reaction the blood vessels were widened and often more tortuous than on the control side This was observed in the formation of circumferential lamellae In stronger reactions which occurred by formation of primary osteones several layers of dilated and tortuous vessels were seen In the strongest reaction long slightly tortuous vessels were observed with pronounced calibre variation running practically perpendicular to the bone surface The blood vessels anastomosed with each other in a U shaped fashion at varying heights often immediately outside the original cortex These blood vessels were present where trabecular bone was being formed (See color pl 2 a)

vessels. In two young animals (51-52) cavities were seen in the callus at the insertion of the fibula on the tibia. The blood vessels in the cavity showed essentially the same appearance as in normal medullary tissue.

Cortex In the outer cortex many of the blood vessels were wider on the treated side than on the control side. Several wide vessels, often massively filled with Indian ink, were seen to run from the periosteum through the cortex to the medullary cavity. The Indian ink columns in these vessels were about $40\ \mu$ in diameter. The cortex lying immediately under the callus cavities was sparsely revascularized by fairly thin blood vessels. In the deeper parts of the cortex here there was a complete absence of Indian ink filled vessel.

Medullary cavity In all animals blood vessels were seen to emerge from almost all parts of the cortex. Wide vessels, as a rule veins, were observed in three of the seven growing and two of the five adult animals. In the centre of the medullary cavity in the growing animals occasional immature blood vessels were seen of the type described at an observation time of 1 week, viz. polygonal of varying calibre and massively filled with Indian ink. Peripheral to this area there was a large number of mutually anastomosing blood vessels of circular cross section and with a diameter of $30-40\ \mu$. These vessels formed a network with meshes measuring about $70\ \mu$. Woven bone was seen between the vessels. In other areas of the medullary cavity there were sparsely located narrow, somewhat tortuous vessels of equal calibre which in the form of a brush ran in one direction. The tissue structure between these blood vessels appeared on the angiography preparations to be homogeneous. Adjacent to the endosteum there were long blood vessels about $100\ \mu$ wide with a circular cross section and lined with grains of Indian ink. These wide vessels lay in direct contact with intermediately located bone trabeculae (Fig. 24). Alternating with these wide vessels adjacent to the endosteum straight vessels about $50\ \mu$ thick and massively filled with Indian ink were seen.

Blood vessels from the medullary cavity returned to avascular parts of the cortex and revascularized the inner part of the cortex.

Observation time 8 weeks

Periosteum The periosteal vascular reaction appeared to have disappeared completely. No difference in the width or tortuosity of the blood vessels or of the depth of the vascular layer was found on comparison between the treated and control sides. The blood vessels in the newly formed periosteal bone had assumed a completely mature appearance.

Cortex The difference between the angiographic pattern in the outer and inner parts of the cortex was pronounced. In the outer cortical regions most

Fig 23 Distal Spalteholz section observation time 2 weeks Growing animal 281 Newly formed blood vessels are seen in the medullary cavity In some areas the endosteal part of the cortex is not yet revascularized

lined with Indian ink were often observed When this vascular reaction occurred from the surface of the original cortex a pronounced vascular reaction was usually observed at the same time in the overlying periosteum

Medullary cavity The vascular reaction in the medullary cavity was similar to that observed at 1 week Newly formed blood vessels were seen in the medullary cavity in all animals except one young animal (45) In only one case (281) (Fig 23) were blood vessels seen to emerge from the cortex at a location where the endosteal bone had been directly damaged by the rotating reamer In the other cases the blood vessels emerged from the cortex in the non reamed areas

Observation time 4 weeks

Periosteum The reaction in the periosteal blood vessels had diminished considerably and was only observed in one of the six young animals (97) and one of the five adults (89) The vascular density in the subperiosteal bone which had developed after the reaming had decreased greatly The blood vessels had also decreased in diameter had become straighter and had assumed essentially the same appearance as the deeper located intracortical

with thick walls were observed in all young animals and in three of the six adults. In addition to the type of blood vessels described for the 4 week preparations normal sinusoids were also seen in all animals.

Observation time 12 weeks

Periosteum The periosteal blood vessels had the same appearance on the treated side as on the control side.

Cortex Three of the five animals showed revascularized cortex. Even in these animals however small areas of central cortex which had not been invaded by blood vessels were seen.

Medullary cavity In the medullary cavity in all animals areas with normal sinusoids were found. In many animals however there were areas which had not been revascularized. The types of blood vessels described for the 4 week and 8 week preparations were also found at this observation time. The immature vessels observed at 1 week were not seen in the 12 week preparations however.

Discussion

Reaction in Periosteum

Three days after reaming of the medullary cavity a distinct reaction was observed in the periosteal blood vessels especially in the young animals. These blood vessels had become wider and more tortuous and were filled more massively with Indian ink than on the control side. Kookenberg (1963) observed this vascular reaction one week after fracture in the rabbit tibia. He called these vessels type 1 and considered that they represented hyperaemia in existing blood vessels.

The blood vessel type which Kookenberg named type 2 consisted of mutually parallel vessels perpendicular to the bone surface which initially showed varying calibres but which after about 2 weeks were found to be of equal width. Kookenberg found this vascular reaction in his preparations 2 and 4 weeks after fracture in the rabbit tibia. In the present material such blood vessels were observed between periosteum and cortex in those cases where fluorescent preparations showed that trabecular bone had been formed. The underlying cortex was then as a rule avascular. Göthman (1961) observed this vascular reaction subperiosteally 2-6 weeks after nail ing of rabbit tibiae without fracture "in only a few cases". The typical pattern with blood vessels of type 2 is eliminated when the bone is reconstructed. A similar vascular reaction can sometimes be seen in the medullary cavity on the formation of a homogeneous fibrous tissue. In the present

Fig 24 Proximal Spalteholz cross section observation time 4 weeks Growing animal 15 Three different vascular areas can be seen in the medullary cavity. Nearest to the central extravasation of Indian ink there are small areas penetrated by narrow vessels (fibrotic areas). Peripheral to these areas there is a broad zone of wider vessels between lighter zones (bone trabeculae). Nearest to the endosteum a small number of light zones (bone trabeculae) surrounded by wide Indian ink filled vessels are seen. In the innermost part of the cortex resorption cavities are observed especially fibularly.

vessels showed a normal appearance but some wide vessels connecting the vessels of the periosteum and those of the medullary cavity were observed. In the inner part of the cortex a large number of wide vessels were found often located in resorption cavities in the bone. These blood vessels communicated with the medullary cavity by a large number of vessels of fairly wide calibre. Blood vessels were found in almost the entire cortex in all growing and in two of the six adult animals but between the vessels in the inner part of the cortex there were small areas of bone tissue which were not revascularized. In this area several bone canals contained two blood vessels one of which was narrow and massively filled with Indian ink while the other was wider with Indian ink only lining its walls.

Medullary cavity. Blood vessels were found in the medullary cavity in all animals. In all animals except one (83) blood vessels were seen to have invaded the medullary cavity even from endosteal bone which had been damaged by the reamer. Vessels of wide calibre in some cases arteries

with thick walls were observed in all young animals and in three of the six adults. In addition to the type of blood vessels described for the 4 week preparations, normal sinusoids were also seen in all animals.

Observation time 12 weeks

Periosteum The periosteal blood vessels had the same appearance on the treated side as on the control side.

Cortex Three of the five animals showed revascularized cortex. Even in these animals, however, small areas of central cortex which had not been invaded by blood vessels were seen.

Medullary cavity In the medullary cavity in all animals, areas with normal sinusoids were found. In many animals, however, there were areas which had not been revascularized. The types of blood vessels described for the 4 week and 8 week preparations were also found at this observation time. The immature vessels observed at 1 week were not seen in the 12 week preparations, however.

Discussion

Reaction in Periosteum

Three days after reaming of the medullary cavity, a distinct reaction was observed in the periosteal blood vessels, especially in the young animals. These blood vessels had become wider and more tortuous and were filled more massively with Indian ink than on the control side. Kookenberg (1963) observed this vascular reaction one week after fracture in the rabbit tibia. He called these vessels type 1 and considered that they represented hyperaemia in existing blood vessels.

The blood vessel type which Kookenberg named type 2 consisted of mutually parallel vessels perpendicular to the bone surface which initially showed varying calibres but which after about 2 weeks were found to be of equal width. Kookenberg found this vascular reaction in his preparations 2 and 4 weeks after fracture in the rabbit tibia. In the present material, such blood vessels were observed between periosteum and cortex in those cases where fluorescent preparations showed that trabecular bone had been formed. The underlying cortex was then, as a rule, avascular. Gothman (1961) observed this vascular reaction subperiosteally 2-6 weeks after nailing of rabbit tibiae without fracture, in only a few cases. The typical pattern with blood vessels of type 2 is eliminated when the bone is reconstituted. A similar vascular reaction can sometimes be seen in the medullary cavity on the formation of a homogeneous fibrous tissue. In the present

study the vascular reaction in the periosteum was most pronounced at an observation time of 2 weeks it had decreased at 4 weeks and was completely absent at 8 weeks

At observation times of less than 1 week subperiosteal haemorrhages were often seen within the area of insertion of the fibula on the tibia. As a rule no Indian ink had leaked into these haemorrhages, indicating that they had occurred before the Indian ink angiography. Subperiosteal haemorrhages were sometimes also found in other areas of the diaphysis. The reason for these haemorrhages will be discussed in chapter 4. On preparations observed at 1 week or later, no subperiosteal haemorrhages were seen and it is probable that they had been resorbed. Within the area in which they were usually found trabecular bone was often observed instead.

On the resorption of bone trabeculae in the central parts of newly formed trabecular bone under the periosteum, wide, round blood vessels of equal thickness and parallel with the peripheral surface of the original cortex were found. These vessels were of the same type as occurred in the medullary cavity on resorption of the bone beams there. In both cases this type of blood vessel was often later replaced by normal sinusoids.

Reaction in Cortex

The first vascular reaction in the cortex was widening of the blood vessels in that part of the outer cortex in which the blood circulation was still present after reaming of the medullary cavity. A tendency towards this reaction was found in young animals at an observation time of 3 days, and the reaction was pronounced at 1 week. The blood vessels appeared first to become wider in the bone canals without the latter being changed but later the bone canals also increased in calibre. Rhinelander & Baragry (1962) considered that parts of the intracortical capillary network were normally resting but that on increased functional demands e.g. following a fracture of the contralateral bone the blood vessels opened and thus could be filled with contrast medium. Gothman (1961) and Brookes (1964) found that Micropack suspension did not pass into the cortex from periosteal vessels until about 1 week after a disturbance of the endosteal circulation in the rabbit. Brookes considered that the intracortical vessels increased in calibre due to reversal of the normal blood flow. The present experiments indicated that immediately after reaming of the medullary cavity the blood vessels passing from the periosteum into the cortex were able to lead blood into the cortex and that these vessels then became successively wider. The deficiency in vascular filling with contrast medium observed by Rhinelander & Baragry and other workers was probably due to the fact that Micropack

has difficulty in passing through these blood vessels before they have increased in calibre which does not take place to a sufficient degree until about one week after the operation. Some of the blood vessels in the outer cortex continued to increase in width during the 12 weeks of the present experiments. Other vessels which had increased in size during the first weeks after the intramedullary reaming appeared to decrease again in calibre after about 4 weeks at the same time as their bone canals became narrower. The circulation from the periosteum into the cortex thereby became more and more concentrated to a smaller number of increasingly wide vessels while the majority of blood vessels in the outer part of the cortex got the same appearance as on the control side.

The reaction in the inner part of the cortex depended upon whether or not the area had retained its circulation after the reaming. In those areas which had retained their circulation the blood vessels appeared to react in the same way as in the outer vascularized part of the cortex. From the borderline area between those parts of the cortex in which the blood vessels still functioned after reaming of the medullary cavity and those which no longer functioned special vascular reactions were observed after about 2 weeks. These appeared to be of two types: either a ball of blood vessel loops was formed which comprised the vascular component in a "cutter head" or a fairly large broom shaped bundle of vessels. Around the bundle of blood vessels so much bone was sometimes resorbed in young animals that a very large cavity was formed in the cortex. Arciform blood vessels could then be seen passing to the underlying bone in which resorption was taking place. The "cutter heads" and bundles of blood vessels widened canals or cavities in the direction towards the medullary cavity and in this way revascularized the cortex. At this stage their vascular communication was only with the periosteal blood vessels.

Reaction in Medullary Cavity

On the first few days after the operation most preparations showed occasional blood vessels which passed from the periosteum through the entire cortex as far as the medullary cavity. These vessels were seen in areas which had not been damaged directly by the rotating reamer. That these blood vessels really were functioning for the transport of fluid was shown by fluorescence preparations from animal 124 at an observation time of 1 day. This animal had been given tetracycline 24 hours after the operation. The tetracycline had diffused out into the medullary cavity around a blood vessel which had opened on the endosteal surface and had become bound to bone fragments immediately outside the vessel. The tetracycline

had then not become reabsorbed into the circulation but was visible on the fluorescence preparation. The binding of tetracycline to the bone fragments was probably due to the fact that they were becoming halisteretic by lying in an acid environment. In the development of halisteresis there is a release of calcium ions, and if these are not removed owing to a poor circulation tetracycline can become bound to them (Eger & Kammerer, 1967) See p 48 Fig 11

The first blood vessels to develop in the medullary cavity were observed at an observation time of 1 week. These vessels were irregular in shape and varied in calibre, and formed a three dimensional network. They closely resembled the type referred to by Koekenberg as type 3. Koekenberg found type 3 blood vessels during fracture healing in the rabbit at an observation time of 2-7 weeks and considered that they were associated with chondral ossification. In the present material they were always the first blood vessels to form on revascularization of subperiosteal haematomas or of the medullary cavity. In no preparation was cartilage formation observed. Often in places where blood vessels had invaded the medullary cavity from the cortex a narrow blood vessel massively filled with contrast medium which was considered to be an artery was observed, as well as several round blood vessels lined with grains of Indian ink, which were considered to be veins. The bone formation in the medullary cavity did not appear to take place in direct association with the types of blood vessel referred to by Koekenberg as type 3, but later when round vessels of medium calibre and anastomosing in network form had developed. Within the meshes of the network, between these blood vessels woven bone was formed. Resorption of bone trabeculae in the medullary cavity appeared to take place near to 100 μ wide anastomosing round blood vessels which bordered closely on the surface of these beams. After resorption of the bone trabeculae the blood vessels underwent a change to apparently normal sinusoids.

On Indian ink filling of intracortical vessels by the method described here, the entire vascular bed including the capillaries became filled. The method is therefore suitable when the nutritive flow in the cortex is to be studied, but does not allow determination of the direction of the blood flow on a material not subjected to operation. This has also been pointed out by Brookes (1960).

STUDY OF THE EXTENT OF INTRACORTICAL VASCULAR DAMAGE

Previous investigations concerning the capacity of the periosteal vessels to take over the intracortical circulation when the contents of the medullary

cavity have been destroyed have given varying results (see chapter 1) It was therefore considered of interest to study by means of Indian ink angiography and the Spalteholz technique the extent of the intracortical vascular damage that occurs after reaming of the medullary cavity and to follow the revascularization of the cortex Indian ink angiography gives good visualization of the intracortical vessels even one day after the operation and with the Spalteholz technique it is possible to study the Indian ink filling by stereomicroscopy and to record the vascular front (see p 30)

Material and Methods

The material comprised the 67 animals—36 growing and 31 adults—shown in Table 1 which were studied at observation times of 1–3 days 1 week 2 weeks 4 weeks 8 weeks and 12 weeks Animal 81 in which angiography was not performed was not included From animals with observation times of 1–3 day two angiography sections from the diaphysis were examined—one about 2.8 cm and one about 7.3 cm from the tibiotalar joint From the remaining animals sections from the distal part of the diaphysis were examined The percentual part of the original cortex (area BE) which lacked Indian ink filled vessels (area CD) was recorded

The areas of the section in which the vessels were filled with Indian ink were called vascularized cortex and those which lacked Indian ink filled vessels avascular cortex The borderline between Indian ink filled and non Indian ink filled areas was called the vascular front

At observation times of 8 and 12 weeks many vessels were observed which first penetrated through the cortex into the medullary cavity and then invaded the cortex within another area The cortex was thus revascularized also from the medullary cavity Vessels were then found in the cortex both close to the medullary cavity and in the outer part but interlying areas of the cortex could lack blood vessel In these cases the assessment of the surface of avascular bone on the basis of the vascular front was not reliable and the percentual part of the cortical surface which was avascular had to be estimated instead

Results

The mean values of the percentage of avascular cortex within each experimental group are given in Table 3 a for growing animals and in Table 3 b for adult animals The tables also show the ranges of variation within the different groups

From the table for growing animals can be seen that in the group observed at 1–3 days 26% of the cross section area of the cortex was avascu

had then not become reabsorbed into the circulation but was visible on the fluorescence preparation. The binding of tetracycline to the bone fragments was probably due to the fact that they were becoming halisteretic by lying in an acid environment. In the development of halisteresis there is a release of calcium ions and if these are not removed owing to a poor circulation, tetracycline can become bound to them (Eger & Kammerer, 1967) See p 48 Fig 11

The first blood vessels to develop in the medullary cavity were observed at an observation time of 1 week. These vessels were irregular in shape and varied in calibre, and formed a three dimensional network. They closely resembled the type referred to by Koekenberg as type 3. Koekenberg found type 3 blood vessels during fracture healing in the rabbit at an observation time of 2-7 weeks, and considered that they were associated with chondral ossification. In the present material they were always the first blood vessels to form on revascularization of subperiosteal haematomas or of the medullary cavity. In no preparation was cartilage formation observed. Often in places where blood vessels had invaded the medullary cavity from the cortex a narrow blood vessel massively filled with contrast medium which was considered to be an artery, was observed as well as several round blood vessels lined with grains of Indian ink which were considered to be veins. The bone formation in the medullary cavity did not appear to take place in direct association with the types of blood vessel referred to by Koekenberg as type 3, but later when round vessels of medium calibre and anastomosing in network form had developed. Within the meshes of the network, between these blood vessels woven bone was formed. Resorption of bone trabeculae in the medullary cavity appeared to take place near to 100 μ wide anastomosing round blood vessels, which bordered closely on the surface of these beams. After resorption of the bone trabeculae the blood vessels underwent a change to apparently normal sinusoids.

On Indian ink filling of intracortical vessels by the method described here, the entire vascular bed including the capillaries became filled. The method is therefore suitable when the nutritive flow in the cortex is to be studied but does not allow determination of the direction of the blood flow on a material not subjected to operation. This has also been pointed out by Brookes (1960).

STUDY OF THE EXTENT OF INTRACORTICAL VASCULAR DAMAGE

Previous investigations concerning the capacity of the periosteal vessels to take over the intracortical circulation when the contents of the medullary

Discussion

During the first hours after reaming of the medullary cavity incomplete filling of the intracortical vessels is obtained on angiography with Indian ink (see p 67) but after about 24 hours the visualization is so good that the vascular front can be recorded. Revascularization of the cortex takes place from residual intracortical vessels which are supplied from periosteal vessels. According to Axhausen & Bergmann (1937) the first budding of new vessels on revascularization of a fracture area begins at the end of the second day. The percentage of avascular cortex which is recorded on sections at observation times of 1-3 days should therefore give a good reflection of the vascular damage caused by reaming of the medullary cavity. In this material about 30 % of the cortical cross section was avascular both within the distal and proximal part of the diaphysis. If this corresponds to the area of the cortex which cannot be supplied by the periosteal vessels when the medullary cavity is destroyed these findings are in disagreement with several previous results. Thus de Marneffe (1953) claims that within the distal part of the tibial diaphysis in the rabbit the cortex is supplied to the largest part from periosteal vessels while in the proximal part of the diaphysis only the outer part of the cortex is supplied from these vessels. Trueta & Cavadias (1955) found in rabbits that only the outer third of the cortex was supplied from periosteal vessels and the rest from endosteal vessels. In the experimental studies of these latter authors however considerable pressure may have occurred in the medullary cavity when the metaphyses were plugged which may have caused damage to the intracortical vessels (see p 110). As a perfusion medium they used mainly Micropack which probably gives poorer filling of the cortical vessels than Indian ink. These factors may explain their different results.

The vascular damage in the cortex was possibly somewhat greater in the adults than in the growing animals. Since the vessels in the subperiosteal bone are narrower in the adults than in the growing animals this difference may be due partly to the fact that the Indian ink suspension did not fill the intracortical vessels so completely in the adult animals despite the fact that these had functioned intravitaly.

The variations in that part of the cortex which became avascular between the different animals and between different sectors in the same animal was so great that the avascularity could not have been due solely to occlusion of the blood supply from the medullary cavity but must also have had other causes. This will be discussed in chapter 4.

At an observation time of 8 weeks the cortex in the growing animals was completely revascularized. This finding was made by Trueta & Cavadias

lar The avascularity was fairly evenly distributed within the four sectors. The values for the proximal and the distal sections corresponded well. The range of variation was very wide in the distal section between 9% and 61%. The variation was smaller in the proximal sections. In one animal (125) the whole of the tibial sector of the distal section was vascularized. At observation times of longer than 2 weeks there was a tendency for a smaller part of the cortex to be avascular. Thus at 4 weeks there were two animals in which the whole of the cortical cross section area was revascularized (7/216) and at 8 weeks all growing animals showed complete revascularization of the cortex.

The adult animals had a somewhat higher mean percentage of avascular cortex at an observation time of 1-3 days both in the distal and proximal section than the growing animals. Also in the adult group a very large variation was found between individual animals. There was some tendency for the lowest percentage of avascular cortex in any animal in an experimental group to decrease with increasing observation times. At an observation time of 8 weeks two animals showed completely revascularized cortex (67/77) while in the others between 5% and 20% of the cortex was estimated to be still avascular. At 12 weeks two animals (70/76) showed revascularized cortex and in the other three about 10% of the cortex was avascular.

Discussion

During the first hours after reaming of the medullary cavity incomplete filling of the intracortical vessels is obtained on angiography with Indian ink (see p 67) but after about 24 hours the visualization is so good that the vascular front can be recorded. Revascularization of the cortex takes place from residual intracortical vessels which are supplied from periosteal vessels. According to Axhausen & Bergmann (1937) the first budding of new vessels on revascularization of a fracture area begins at the end of the second day. The percentage of avascular cortex which is recorded on sections at observation times of 1-3 days should therefore give a good reflection of the vascular damage caused by reaming of the medullary cavity. In this material about 30% of the cortical cross section was avascular both within the distal and proximal part of the diaphysis. If this corresponds to the area of the cortex which cannot be supplied by the periosteal vessels when the medullary cavity is destroyed, these findings are in disagreement with several previous results. Thus de Marneffe (1953) claims that within the distal part of the tibial diaphysis in the rabbit the cortex is supplied to the largest part from periosteal vessels while in the proximal part of the diaphysis only the outer part of the cortex is supplied from these vessels. Trueta & Cavadias (1955) found in rabbits that only the outer third of the cortex was supplied from periosteal vessels and the rest from endosteal vessels. In the experimental studies of these latter authors however considerable pressure may have occurred in the medullary cavity when the metaphyses were plugged which may have caused damage to the intracortical vessels (see p 110). As a perfusion medium they used mainly Micropack which probably gives poorer filling of the cortical vessel than Indian ink. These factors may explain their different results.

The vascular damage in the cortex was possibly somewhat greater in the adults than in the growing animals. Since the vessels in the subperiosteal bone are narrower in the adults than in the growing animals this difference may be due partly to the fact that the Indian ink suspension did not fill the intracortical vessels so completely in the adult animals despite the fact that these had functioned intravitaly.

The variations in that part of the cortex which became avascular between the different animals and between different sectors in the same animal was so great that the avascularity could not have been due solely to occlusion of the blood supply from the medullary cavity but must also have had other causes. This will be discussed in chapter 4.

At an observation time of 8 weeks the cortex in the growing animals was completely revascularized. This finding was made by Trueta & Cavadias

lar The avascularity was fairly evenly distributed within the four sectors. The values for the proximal and the distal sections corresponded well. The range of variation was very wide in the distal section between 9% and 61%. The variation was smaller in the proximal sections. In one animal (125) the whole of the tibial sector of the distal section was vascularized. At observation times of longer than 2 weeks there was a tendency for a smaller part of the cortex to be avascular. Thus at 4 weeks there were two animals in which the whole of the cortical cross section area was revascularized (7, 216) and at 8 weeks all growing animals showed complete revascularization of the cortex.

The adult animals had a somewhat higher mean percentage of avascular cortex at an observation time of 1-3 days both in the distal and proximal section than the growing animals. Also in the adult group a very large variation was found between individual animals. There was some tendency for the lowest percentage of avascular cortex in any animal in an experimental group to decrease with increasing observation times. At an observation time of 8 weeks two animals showed completely revascularized cortex (67, 77) while in the others between 5% and 20% of the cortex was estimated to be still avascular. At 12 weeks two animals (70, 76) showed revascularized cortex and in the other three about 10% of the cortex was avascular.

Discussion

During the first hours after reaming of the medullary cavity incomplete filling of the intracortical vessels is obtained on angiography with Indian ink (see p 67) but after about 24 hours the visualization is so good that the vascular front can be recorded. Revascularization of the cortex takes place from residual intracortical vessels which are supplied from periosteal vessels. According to Axhausen & Bergmann (1937) the first budding of new vessels on revascularization of a fracture area begins at the end of the second day. The percentage of avascular cortex which is recorded on sections at observation times of 1-3 days should therefore give a good reflection of the vascular damage caused by reaming of the medullary cavity. In this material about 30 % of the cortical cross section was avascular both within the distal and proximal part of the diaphysis. If this corresponds to the area of the cortex which cannot be supplied by the periosteal vessels when the medullary cavity is destroyed these findings are in disagreement with several previous results. Thus de Marneffe (1953) claims that within the distal part of the tibial diaphysis in the rabbit the cortex is supplied to the largest part from periosteal vessels while in the proximal part of the diaphysis only the outer part of the cortex is supplied from these vessels. Trueta & Cavadias (1955) found in rabbits that only the outer third of the cortex was supplied from periosteal vessels and the rest from endosteal vessels. In the experimental studies of these latter authors however considerable pressure may have occurred in the medullary cavity when the metaphyses were plugged which may have caused damage to the intracortical vessels (see p 110). As a perfusion medium they used mainly Micropack which probably gives poorer filling of the cortical vessels than Indian ink. These factors may explain their different results.

The vascular damage in the cortex was possibly somewhat greater in the adults than in the growing animals. Since the vessels in the subperiosteal bone are narrower in the adults than in the growing animals this difference may be due partly to the fact that the Indian ink suspension did *not* fill the intracortical vessels so completely in the adult animals despite the fact that these had functioned intravitaly.

The variations in that part of the cortex which became avascular between the different animals and between different sectors in the same animal was so great that the avascularity could not have been due solely to occlusion of the blood supply from the medullary cavity but must also have had other causes. This will be discussed in chapter 4.

At an observation time of 8 weeks the cortex in the growing animals was completely revascularized. This finding was made by Trueta & Cavadias

(1955) after an observation time of 7 weeks in growing rabbits. In adult rabbits avascular parts of the cortex were still seen in many cases after observation times of both 8 and 12 weeks.

STUDY OF THE AMOUNT OF NEWLY FORMED PERIOSTEAL BONE

Material

The material consisted of 39 rabbits. 22 of which were growing animals and 17 adults. The material comprised those animals in Table 1 in which one tibia was operated on, the other tibia serving as a control. The observation times, i.e. the lengths of time after the operation to the angiography, were 1, 2, 4 and 8 weeks. Growing animals in which labelling 1 (see p. 25) was performed at time points 0-2 days after reaming of the medullary cavity and adult animals in which labelling 1 was performed 1-4 days after the operation were included. The two growing animals, 6 and 7 and the adult animal 75, in which labelling 1 was not performed until 7 days after the reaming were thus not included.

Method

The area of the newly formed periosteal bone (area *AB*) was calculated on the distal transverse fluorescence section from approximately 3.3 cm above the tibiotalar joint (see p. 36). Area *AB* is expressed as a percentage of the area of the original cortex (area *BE*). The calculation was made separately for each sector and also for the whole cross section on the treated side and on the control side. In the calculation of the whole cross section the sum of *AB* from the four sectors is expressed in per cent of the sum of *BE* from the four sectors. A sector from the treated side and the corresponding sector from the control side are called a pair of sectors. The section from the treated side and the section from the control side are called a pair of sections. The percentage value obtained for the periosteally formed new bone is called within each sector the bone formation value (BF). The mean bone formation value for all animals in an experimental group is denoted the mean bone formation (MBF). The term *Z* is added when the whole cross section has been calculated, the term *C* when the calculation refers to the control side and *O* when it refers to the treated side. For example MBFZC = mean bone formation for the whole sections on the control side in one experimental group.

The difference between the bone formation values on the treated and control sides within each pair of sectors is called the bone formation difference (BFD). The mean bone formation difference for all animals in an experimental group is denoted the mean bone formation difference (MBFD). The term *Z* is used in the same way as in the calculation of the bone formation values.

Significance testing of the difference in periosteal bone formation between the main experimental groups was performed by means of the Wilcoxon test (see *Documenta Geigy* 6th ed. p. 124).

Fig 25 Growing animals Mean periosteal bone formation (area AB) in per cent of the area of the original cortex (area BE) in the whole section in the experimental groups with observation times of 1 to 8 weeks ●—● treated bone (MBFZO) ○—○ control bone (MBFZC) □—□ difference between treated and control bone (MBFDZ)

Results

Growing Animals (Fig 25)

Observation time 1 week MBFZC was 1.1° BFZC varied between the individual animals from 0.4–1.6

MBFDZ was 0.6 / BFDZ varied between the individual animals from 0.1 to 1.3 ° MBFD was greatest in the ventral sector (0.9°) and smallest in the fibular sector (0.3°) BFD was greatest (1.8 /) in the tibial sector in animal 95 and smallest (–0.2°) in the dorsal and tibial sectors in animal 106

Observation time 2 weeks MBFZC was 1.6 BFZC varied between the individual animals from 0.4 to 3.0%

MBFDZ was 4.5 / BFDZ varied between the individual animals from 0.3 to 10.5% MBFD was greatest in the fibular sector (8.2°) and smallest in the ventral sector (2.8°) BFD was greatest (31.1°) in the fibular sector in animal 281 and smallest (–0.1°) in the ventral sector in animal 101

Observation time 4 weeks MBFZC was 10.2%. BFZC varied between the individual animals from 3.2% to 33.5%

MBFDZ was 15.5%. BFDZ varied between the individual animals from 0.4 to 60.8%. MBFD was greatest in the fibular sector (20.5%) and smallest in the tibial sector (8.5%). BFD was greatest (82.0%) in the fibular sector in animal 52 and smallest (-1.4%) in the ventral sector in animal 216

Observation time 8 weeks MBFZC was 8.1%. BFZC varied between the individual animals from 2.6 to 19.7%

MBFDZ was 5.0%. BFDZ varied between the individual animals from 3.0 to 8.0%. MBFD was greatest in the fibular sector (8.2%) and smallest in the tibial sector (2.7%). BFD was greatest (15.8%) in the dorsal sector in animal 111 and smallest (-0.2%) in the tibial sector in animal 65

In the group observed at 1 week only small amounts of bone had been formed subperiosteally, both on the treated and the control side

On comparison between the groups observed at 1 and 2 weeks, an increase in the area of newly formed bone was found on the treated side, which was significant at the 5% level while the bone area on the control side had increased only very slightly. A significant difference at the 10% level was found between the treated and the control side in the group observed at 2 weeks

On comparison between the groups observed at 2 and 4 weeks, a further increase in the mean bone area on the treated side was found. This increase was due largely to the considerable bone formation in one animal (52) and is not significant. On the control side the bone area had increased significantly at the 1% level on comparison between the same groups of animals. No significant difference was found between the treated and control side in the group observed at 4 weeks

Comparison between the groups of animals observed at 4 and 8 weeks showed no significant difference in the area of newly formed bone either on the treated or on the control side

Adult Animals (Fig. 26)

Observation time 1 week MBFZC = 0.2%. BFZC varied between the individual animals from 0 to 0.7%

MBFDZ was 0.4%. BFDZ varied between the individual animals from 0.1 to 0.9%. MBFD was greatest in the ventral sector (0.7%) and smallest in the fibular sector (0.0%). BFD was greatest (2.1%) in the ventral sector in animal 121 and smallest (-0.1%) in the fibular sector in animal 121

Fig 26 Adult animals Mean periosteal bone formation (area AB) in per cent of the area of original cortex (area BE) in the whole section in the experimental groups with observation times of 1 to 8 weeks (For notation see Table 25)

Observation time 2 weeks MBFZC was 0.2°. BFZC varied between the individual animals from 0.0 to 0.8°.

MBFDZ was 5.5°. BFDZ varied between the individual animals from 0.3 to 21.8°. MBFD was greatest in the dorsal sector (7.1°) and smallest in the ventral sector (2.9°). BFD was greatest (24.3°) in the dorsal sector in animal 86 and smallest (-0.2°) in the fibular sector in animal 58.

Observation time 4 weeks MBFZC was 0.3°. BFZC varied between the individual animals from 0 to 1.0°.

MBFDZ was 2.5°. BFDZ varied between the individual animals from 0.3 to 6.9°. MBFD was greatest in the tibial sector (4.7°) and smallest in the fibular sector (1.3°). BFD was greatest (16.7°) in the tibial sector in animal 89 and smallest (0.0°) in the dorsal sector in animal 88.

Observation time 8 weeks MBFZC was 1.0°. BFZC varied between the individual animals from 0.7 to 1.6°.

MBFDZ was 4.6°. BFDZ varied between the individual animals from 1.2 to 7.6°. MBFD was greatest in the ventral sector (7.2°) and smallest in the fibular sector (2.9°). BFD was greatest (13.3°) in the dorsal sector in animal 85 and smallest (0.1°) in the dorsal sector in animal 77.

On comparison between the groups observed at 1 and 2 weeks and between those observed at 2 and 4 weeks, no significant difference in the area of newly formed bone was found either on the treated or the control side. The high mean value for the bone formation on the treated side at an observation time of 2 weeks was mainly due to the large amount of new bone formed in one animal 86.

Comparison of the bone formation in the combined groups observed at 1, 2 and 4 weeks with that in the group observed at 8 weeks showed a significant increase at the 5% level on the treated side and a significant in

crease at the 2% level on the control side. The difference in area of newly formed bone between the treated side and control side on comparison between these groups was significant at the 10% level.

Discussion

With the method of recording used, measurements were made of the cross sectional area of the periosteal tissue whose bone component was mineralized within 8 hours after labelling ^{45}Ca (see p 33). This area comprised bone tissue with varying percentages of vessels and perivascular tissue (vascular tissue). If circumferential lamellae has been formed there is approximately the same percentage of vascular tissue as in normal cortical bone. If primary osteones have been formed there is a high percentage of vascular tissue when the osteones are newly formed. The percentage of vascular tissue decreases continuously when the osteones mature and after about 4 weeks the bone tissue has the same percentage of vascular tissue as normal cortical bone. If trabecular bone has been formed the development of the bone tissue can vary. In one case the trabecular bone can be condensed to compact bone and then has a normal percentage of vascular tissue. In another case the central parts of the trabecular bone can instead be broken down and replaced by a richly vascularized cavity (see p 62).

That part of the area of the newly formed bone which consists of actual bone tissue will therefore be dependent upon the length of the observation time and the morphology of the bone.

In this series of experiments the variations between the individual animals in the experimental groups and between the different sectors in the same animal were considerable. In all growing and adult animals the periosteal bone formation in the whole section was greater on the treated than on the control side. In individual pairs of sectors the bone formation was greater on the treated side than on the control side in 82 of the 88 pairs of sectors in growing animals and in 65 of the 68 pairs of sectors in adult animals. Evaluation of the significance of the difference between the different experimental groups was therefore not made on the basis of the mean values and distribution of the mean values of the groups but according to the Wilcoxon test using the order of rank of the measurement values obtained.

After causing a disturbance of the endosteal circulation of the long bone many authors have observed increased periosteal bone formation (Axhausen & Bergmann 1937, Rohlich 1941, Trueta & Cavadias 1955, Kuntscher 1957, Richany *et al* 1965, Mital & Cohen 1966, Flatmark 1967, Zucman *et al* 1968). These investigators have assessed the increased bone

mass histologically or by repeated radiographic studies during the course of the experiment

With histological techniques the boundary between the original cortex and the newly formed periosteal bone can only be established with certainty if the newly formed bone has a different morphology from that of the original cortex. As a rule therefore the exact borderline cannot be determined if the newly formed bone comprises circumferential lamellae or primary osteones only with certainty if it is trabecular. Acceleration or restimulation of the normal bone formation can then often not be demonstrated with certainty but only the real callus formation.

Repeated radiographic examinations during the course of the experiment cannot as a rule reveal minor changes in the bone mass.

In this investigation two tetracycline injections were given—one at the start of the experiment and the other at its end. In this way the bone formed during the experimental period was delimited. By this method even small amounts of bone could be measured. Similar techniques for the assessment of newly formed bone or dentine have been used by Frost (1963), Tapp (1966), Hansson (1967) and Ahlgren (1968). There appear to have been no previous reports in the literature on the use of bone labelling techniques in studies of the amount of periosteal bone formation after disturbances of the endosteal circulation of the long bone.

During the first week after reaming of the medullary cavity in growing animals only very small amounts of new bone were formed subperiosteally both on the treated and the control side. This first week comprises the adrenergic corticoid postoperative phase for the animal during which an increased quantity of adrenocortical steroids are released which on experimental administration have been found to result in depression of the bone formation (Hulth & Olerud 1964, Tapp 1966). The main bone formation on the treated side in growing animals takes place during the second week of the experiment which should comprise the anabolic postoperative phase. On the control side the main bone formation takes place during the third and fourth weeks postoperatively when the bone formation on the treated side is already declining. At this time the compensation for the previously retarded formation of bone on the control side can begin.

In adult animals the development is more difficult to evaluate. No definite increase in the bone formation is evident between subsequent animal groups either on the treated or the control side.

The results obtained here for growing animals are in agreement with the findings of Richany *et al.* in 1965. By histological methods they observed in young adult cat. that after cleaning of the medullary cavity in the femur the bone mass newly formed periosteally was maximal after an observation

time of 3 weeks and was reduced after a further 3 weeks. In the present material there was no markedly greater bone formation in any particular sector, as was found by Richany *et al* in the region around the linea aspera.

The difference in bone formation within the different pairs of sectors in an individual animal was sometimes greatest within that pair of sectors where, on the treated side, the vascular damage in the underlying cortex was greatest, or where the largest amount of bone had been removed from the endosteal surface. The possible relationship between the amount of newly formed bone and the degree of damage to the underlying cortex will be discussed further in chapter 5.

STUDY OF THE BONE FORMATION ACTIVITY OF THE PERIOSTEUM

After reaming of the medullary cavity the periosteum of the bone is, as a rule, activated to increased bone formation. The bone formation activity was assessed in the present study by (a) recording in each sector whether the outer fluorescent band which occurred from labelling 2 was present or not and (b) measuring in each sector the thickness of this fluorescent band together with bone and osteoid located peripherally to it.

The outer fluorescent band comprises essentially that bone which has been mineralized within 8 hours after the last tetracycline injection (Tapp 1966). The bone and osteoid tissue lying peripheral to the outer fluorescent band was formed during the last 40 hours before the angiographic examination since this examination was performed 2 days after labelling 2. The observed thickness was thus an expression of the bone formation which had taken place during the days immediately preceding the angiographic examination in contrast to the total bone formation which referred to the whole observation time. The measurements were performed with a Zeiss ocular micrometer on the distal transversal fluorescence section at a magnification of 320 times.

The periosteum can be activated at different time points after the operation in different animals and in different sectors in the same animal, and the activity can be of varying strengths. Each sector must therefore be evaluated separately. A sector on the treated side and the corresponding sector on the control side have been called a pair of sectors. To obtain a better idea of the bone formation activity of the periosteum this was studied with the aid of several variables, which are defined below. Thus for each sector and pair of sectors respectively recordings were made of the activity value (A), activity difference (AD), resorption value (R), resorption difference (RD), absolute growth value (G), absolute growth difference (GD) and stan

standardized growth difference (SGD) The mean value for these variables was calculated for all sectors or pairs of sectors in each individual animal and for all sectors or pairs of sectors in all animals in each experimental group

In this series of experiments the aim was to determine in relation to the time of operation (1) when the periosteal bone formation started to increase (2) when the periosteal bone formation was maximal (3) when the difference in bone formation activity between the treated and the control side was maximal and (4) how long the increased bone formation activity persisted

Material

The material consisted of 49 rabbits 28 of which were growing animals and 21 adults These animals comprised those shown in Table 1 in which one tibia was subjected to operation while the other served as a control and for which the observation times were 3 days and 1 2 4 and 8 weeks The five animals 50 56 85 77 and 92 in which no fluorescent bone was observed after labelling 2 were excluded from the material (see p 34)

Methods

Determination of Activity Values and Activity Differences

When the outer fluorescent band occurred in any part of the middle $\frac{1}{4}$ of a sector this sector was called active and when it did not this sector was called inactive An active sector was given the value 1 and an inactive sector the value 0 The value thus given to a sector was called the activity value (A) of the sector A could thus have the value 0 or 1 The mean activity on the treated side or the control side for all four sectors in the same animal was denoted MA MA could have any of the values 0 $\frac{1}{4}$ $\frac{1}{2}$ $\frac{3}{4}$ or 1 The mean activity for all sectors in all animals in an experimental group was denoted MAT (=mean activity total) MAT could have values between 0 and 1

The difference within a pair of sectors between the activity value on the treated side and that on the control side was denoted the activity difference (AD) AD was given the value +1 if the treated side was active and the control side inactive the value -1 if the treated side was inactive and the control side active and the value 0 if both sides were inactive or both active The activity difference for a pair of sectors (AD) could have any of the values -1 0 or +1 The mean activity difference for all four pairs of sectors in one animal was denoted MAD MAD could have any of the values -1 $-\frac{1}{2}$ 0 $+\frac{1}{2}$ or +1 The mean activity difference for all pairs of sectors in all animals within an experimental group was denoted MADT MADT could have values between -1 and +1

A regression analysis was performed of the relation of the activity values and activity differences to the observation times these values or differences being used as dependent or y variables and the length of the observation time and the square of the length of the observation time as independent or x variables In the regression ana-

lysis an observation time of 3 days was given the value 1 1 week the value 2 2 weeks the value 3 4 weeks the value 4 and 8 weeks the value 5 The calculations were performed by means of a computer (Uppsala Computer Centre)

Determination of Absolute Growth Values and Absolute Growth Differences

In each sector the maximal thickness of the outer fluorescent band together with bone and osteoid lying peripheral to it was measured within the middle $\frac{1}{4}$ of the sector For each sector the value obtained on measurement was called the absolute growth value (G) The mean of the absolute growth values for all four sectors in the same animal was called the mean absolute growth value (MG) The mean of the absolute growth values for all sectors in all animals in one experimental group was denoted MGT The difference between the absolute growth values on the treated and control sides in each pair of sectors was called the absolute growth difference (GD) The mean of the absolute growth differences for all four sectors in the same animal was called the mean absolute growth difference (MGD) The mean of the absolute growth differences for all four sectors in all animals in an experimental group was denoted MGD_T

Determination of Standardized Growth Difference

In a simple calculation of the mean value for the differences in growth values between the treated and control sides high values within individual sectors e.g. animal 125—dorsal sector will dominate For this reason quantitation of the growth difference to +1 -1 and 0 was performed This was called for each pair of sectors the standardized growth difference (SGD) This was given the value +1 when the thickness on the treated side was significantly greater than on the control side -1 when the thickness on the control side was significantly greater than on the treated side and 0 when the thicknesses on the two sides were the same (see below) SGD could thus be given any of the values 1 0 or -1 The mean value of the standardized growth difference for all pairs of sectors in one animal was denoted MSGD MSGD could have any of the values ± 0 $\pm \frac{1}{4}$ $\pm \frac{1}{2}$ $\pm \frac{3}{4}$ or ± 1 The mean standardized growth difference for all four pairs of sectors in all animals in one experimental group was denoted MSGD_T and could have values between -1 and +1

Determination of Resorption Values and Resorption Differences

When resorption was found within more than half of the periphery of a sector this sector was called a sector undergoing resorption and was given the value 1 while a sector not undergoing resorption was given the value 0 The value given was called the resorption value of the sector (R) The mean resorption values (MR and MRT) the resorption difference (RD) and the mean resorption differences (MRD and MRD_T) were defined and calculated analogously to the corresponding variables used in assessment of the activity

The resorption could only be evaluated in the growing animals since signs of superficial resorption were very unreliable in the adults

Discussion of the Method

In order to assess when the measured growth difference between the right and left side was greater than the expected spontaneous growth difference

Fig 27 Growing animals Correlation between values of activity difference (AD) and standardized growth difference (SGD) in individual animals Coefficient of correlation (R) = 0.21

between the sides the growth difference was studied in five growing rabbits which did not undergo operation. The animals were given tetracycline 2 days before the angiographic examination. The thickness of the newly formed bone was measured in the same way as in the experimental series. The maximal difference of the thicknesses between the sectors within the pairs of sectors was 1 unit (U) = 3.5μ see p 32. Only if one of the sectors in a pair was inactive during simultaneous resorption and the other was active did the maximal difference amount to 2 units. In this series of experiments it was therefore required that in comparisons between sectors in a pair of sectors the difference in the measured thicknesses should be at least 1 unit for an estimated standardized growth difference to be said to exist. If one of the sectors was inactive during simultaneous resorption while the other was inactive the difference should be at least 2 units.

In animals observed at 1 week the fluorescent bands from labellings 1 and 2 were usually confluent. Also the width of the inner fluorescent band from labelling 1 was therefore taken for measurement of the thickness. Since all young animals had a positive activity value in all sectors at an observation time of 3 days it was required in these cases that the thickness should be more than 1 unit for the sector to be considered to have a positive activity value at an observation time of 1 week. The criterion for a positive standardized growth difference was that the difference in thicknesses should be at least 2 units. On evaluation of the absolute growth the whole value obtained for the thickness was used in the calculation. The group of animals observed at 1 week was attributed little importance in the study.

An analysis was performed of the correlations (a) between the activity

lysis an observation time of 3 days was given the value 1 1 week the value 2 2 weeks the value 3 4 weeks the value 4 and 8 weeks the value 5 The calculations were performed by means of a computer (Uppsala Computer Centre)

Determination of Absolute Growth Values and Absolute Growth Differences

In each sector the maximal thickness of the outer fluorescent band together with bone and osteoid lying peripheral to it was measured within the middle 1/3 of the sector For each sector the value obtained on measurement was called the absolute growth value (G) The mean of the absolute growth values for all four sectors in the same animal was called the mean absolute growth value (MG) The mean of the absolute growth values for all sectors in all animals in one experimental group was denoted MGT The difference between the absolute growth values on the treated and control sides in each pair of sectors was called the absolute growth difference (GD) The mean of the absolute growth differences for all four sectors in the same animal was called the mean absolute growth difference (MGD) The mean of the absolute growth differences for all four sectors in all animals in an experimental group was denoted MGD_T

Determination of Standardized Growth Difference

In a simple calculation of the mean value for the differences in growth values between the treated and control sides high values within individual sectors e.g. animal 125—dorsal sector will dominate For this reason quantitation of the growth difference to +1 -1 and 0 was performed This was called for each pair of sectors the standardized growth difference (SGD) This was given the value +1 when the thickness on the treated side was significantly greater than on the control side -1 when the thickness on the control side was significantly greater than on the treated side and 0 when the thicknesses on the two sides were the same (see below) SGD could thus be given any of the values 1 0 or -1 The mean value of the standardized growth difference for all pairs of sectors in one animal was denoted MSGD MSGD could have any of the values ± 0 $\pm 1/3$ $\pm 2/3$ or ± 1 The mean standardized growth difference for all four pairs of sectors in all animals in one experimental group was denoted MSGDT and could have values between -1 and +1

Determination of Resorption Values and Resorption Differences

When resorption was found within more than half of the periphery of a sector this sector was called a sector undergoing resorption and was given the value 1 while a sector not undergoing resorption was given the value 0 The value given was called the resorption value of the sector (R) The mean resorption values (MR and MRT) the resorption difference (RD) and the mean resorption differences (MRD and MRDT) were defined and calculated analogously to the corresponding variables used in assessment of the activity

The resorption could only be evaluated in the growing animals since signs of superficial resorption were very unreliable in the adults

Discussion of the Method

In order to assess when the measured growth difference between the right and left side was greater than the expected spontaneous growth difference

Fig 27 Growing animals Correlation between values of activity difference (AD) and standardized growth difference (SGD) in individual animals Coefficient of correlation (R) = 0.21

between the sides the growth difference was studied in five growing rabbits which did not undergo operation. The animals were given tetracycline 2 days before the angiographic examination. The thickness of the newly formed bone was measured in the same way as in the experimental series. The maximal difference of the thicknesses between the sectors within the pairs of sectors was 1 unit (U) = 3.5μ see p. 32. Only if one of the sectors in a pair was inactive during simultaneous resorption and the other was active did the maximal difference amount to 2 units. In this series of experiments it was therefore required that in comparisons between sectors in a pair of sectors the difference in the measured thicknesses should be at least 1 unit for an estimated standardized growth difference to be said to exist. If one of the sectors was inactive during simultaneous resorption while the other was inactive the difference should be at least 2 units.

In animals observed at 1 week the fluorescent bands from labellings 1 and 2 were usually confluent. Also the width of the inner fluorescent band from labelling 1 was therefore taken for measurement of the thickness. Since all young animals had a positive activity value in all sectors at an observation time of 3 days it was required in these cases that the thickness should be more than 1 unit for the sector to be considered to have a positive activity value at an observation time of 1 week. The criterion for a positive standardized growth difference was that the difference in thicknesses should be at least 2 units. On evaluation of the absolute growth the whole value obtained for the thickness was used in the calculation. The group of animals observed at 1 week was attributed little importance in the study.

An analysis was performed of the correlations (a) between the activity

lysis an observation time of 3 days was given the value 1 1 week the value 2 2 weeks the value 3 4 weeks the value 4 and 8 weeks the value 5 The calculations were performed by means of a computer (Uppsala Computer Centre)

Determination of Absolute Growth Values and Absolute Growth Differences

In each sector the maximal thickness of the outer fluorescent band together with bone and osteoid lying peripheral to it was measured within the middle $\frac{1}{4}$ of the sector For each sector the value obtained on measurement was called the absolute growth value (G) The mean of the absolute growth values for all four sectors in the same animal was called the mean absolute growth value (MG) The mean of the absolute growth values for all sectors in all animals in one experimental group was denoted MGT The difference between the absolute growth values on the treated and control sides in each pair of sectors was called the absolute growth difference (GD) The mean of the absolute growth differences for all four sectors in the same animal was called the mean absolute growth difference (MGD) The mean of the absolute growth differences for all four sectors in all animals in an experimental group was denoted MGD_T

Determination of Standardized Growth Difference

In a simple calculation of the mean value for the differences in growth values between the treated and control sides high values within individual sectors e.g. animal 125—dorsal sector will dominate For this reason quantitation of the growth difference to +1 -1 and 0 was performed This was called for each pair of sectors the standardized growth difference (SGD) This was given the value +1 when the thickness on the treated side was significantly greater than on the control side -1 when the thickness on the control side was significantly greater than on the treated side and 0 when the thicknesses on the two sides were the same (see below) SGD could thus be given any of the values 1 0 or -1 The mean value of the standardized growth difference for all pairs of sectors in one animal was denoted MSGD MSGD could have any of the values ± 0 $\pm \frac{1}{4}$ $\pm \frac{1}{2}$ $\pm \frac{3}{4}$ or ± 1 The mean standardized growth difference for all four pairs of sectors in all animals in one experimental group was denoted MSGD_T and could have values between -1 and +1

Determination of Resorption Values and Resorption Differences

Studies of the Activity Values

Growing animals

For the control side the regression curve for the activity values (A) of the individual sectors was a downward convex parabola which was found to have different strengths in different sectors. For the dorsal and tibial sectors the parabolic form is almost significant but for the ventral and fibular sectors there was only a suggestion of this parabolic form. On the treated side there was a tendency to the same parabolic form in the ventral and dorsal sectors but not in the tibial and fibular sectors. In the regression curve for AD (see Table 6) the tendency to a more curved form on the control side was strongly evident. For the ventral and tibial pairs of sectors there was an upward convex almost significant parabola and in the dorsal and fibular pairs of sectors a suggestion of a parabola of the same appearance. At time point 2.8 (an observation time of 12.6 days) and around this point the AD values were almost significantly increased throughout, which is evident from the coefficient of intercept. At time point 2.8 AD was 0.34 for the ventral sector 0.19 for the dorsal sector 0.31 for the tibial sector and 0.29 for the fibular sector.

The time point for the parabolic maximum was calculated from the formula $t_m = 2.8 - B/2$ which was obtained by derivation of the equation

Fig 28 Adult animals Correlation between values of activity difference (AD) and standardized growth difference (SGD) in individual animals Coefficient of correlation (R) = 0.41

difference (AD) and the standardized growth difference (SGD) and (b) between the absolute growth difference (GD) and the standardized growth difference (SGD)

In growing animals the correlation coefficient (r) between AD and SGD was 0.21 (Fig 27). There was thus a correlation between these methods of recording, but it did not reach the significance level. The weakness of the correlation is due to the fact that activity was also present on the control side in many cases with a positive standardized growth difference, especially in animals with a short observation time. AD would then be equal to 0, but SGD would be greater than 0.

In adult animals the correlation coefficient (r) between AD and SGD was 0.41 (Fig 28). The correlation was thus stronger than in the growing animals but did not reach the significance level. The relatively low r value is due to the fact that an activity difference was found in many sectors, especially in animals with long observation times, where the thickness measured was so small that only small standardized growth differences occurred.

The ratio of the mean value of AD/SGD was 0.33 for growing animals and 1.25 for adult animals, which also illustrates that the reason for the low r value differed partly in growing and adult animals.

The correlation between GD and SGD reached a significant level in both growing and adult animals (Figs 29–30). This is a consequence of the definition of SGD. The diagram shows, however, that when $SGD = 1$ there was considerable variability of GD, especially in the growing animals.

Results

The values obtained on measurement are given in Tables 4 and 5.

Tables 4-5 (cont)

	84	4	0	1	0	0	0	1	0

for the parabola $y = A + B(t - 2.8) + C(t - 2.8)^2$. In the regression curve for AD the time point for the parabolic maximum for the ventral sector was 2.6 for the dorsal sector 2.7 for the tibial sector 2.6 and for the fibular sector 3.3. The difference between the time points for the parabolic maximum within the different sectors was not significant. No evident difference was found in the form of the regression curve for AD between the sum of the reamed sectors (ventral + dorsal) and the sum of the non reamed sectors (tibial + fibular).

Since no marked difference was found between the different sectors or pairs of sectors it seemed suitable to study all sectors combined. The regression curve for MAD (Table 6 Fig. 31) was an ascendingly convex almost significant parabola with its maximum at time point 2.75. At time

Table 6 Results of regression analysis for growing animals with activity difference (AD - MAD) as dependent variable and length of observation time as independent variable

The regression equation is written $(AD - MAD) = A + B(t - 2.8) + C(t - 2.8)^2$. A coefficient of intercept at $t = 2.8$. B regression coefficient for the linear term $(t - 2.8)$. C regression coefficient for the term $(t - 2.8)^2$. The results are given for the difference in each pair of sectors and for the sum of the differences within all 4 pairs of sectors divided by 4 (Mean - MAD). * denotes the degree of significance.

slope throughout but in all sectors significant activity values were found at time point 2.8

In the regression curves for AD (Table 7) the activity values (A) on the treated side at time point 2.8 and around this point predominate so that an almost significant AD value was then found in all sectors. For the tibial and fibular sectors the curve had an almost significant parabolic contour but not for the ventral and dorsal sectors. For the tibial sector the parabola had its maximum at time point 3.1 and for the fibular sector at time point 3.0. No evident difference was found in the shape of the regression curve for AD between the sum of the reamed sectors (ventral + dorsal) and the sum of the non reamed sectors (tibial + fibular).

The regression curve for MAD (Table 7 Fig 32) was an upwardly convex almost significant parabola with a maximum at time point 3.2. Already

point 2 8 MAD was 0 29, which is a significantly increased difference value

A study of the relations of the individual experimental groups shows that at an observation time of 3 days MAT=1 both on the treated and on the control side (Fig 31) On the control side MAT=0 47 at an observation time of 2 weeks The reduction from 1 to 0 47 was highly significant MAT increased to 0 63 at an observation time of 4 weeks and to 1 0 at 8 weeks This increase is not significant

On the treated side MAT=0 78 at an observation time of 2 weeks The decrease from 1 0 at an observation time of 3 days to 0 78 at 2 weeks is almost significant At observation times of 4 and 8 weeks MAT=0 75 The decrease in MAT was so much greater on the control side than on the treated side that MADT was significant at an observation time of 2 weeks

Adult animals

For the control side the regression curve for the activity value (A) of the individual sectors lacked a parabolic shape throughout At time point 2 8 the curve showed a significant downward slope for the dorsal and fibular sectors and a tendency to a downward slope for the ventral sector At this time point none of the sectors on the control side showed a significant A value

For the treated side the regression curve for A lacked a significant parabolic shape throughout At time point 2 8 the curve showed no significant

point 2.8 MAD was 0.29, which is a significantly increased difference value

A study of the relations of the individual experimental groups shows that at an observation time of 3 days $MAT = 1$ both on the treated and on the control side (Fig 31). On the control side, $MAT = 0.47$ at an observation time of 2 weeks. The reduction from 1 to 0.47 was highly significant. MAT increased to 0.63 at an observation time of 4 weeks and to 1.0 at 8 weeks. This increase is not significant.

On the treated side $MAT = 0.78$ at an observation time of 2 weeks. The decrease from 1.0 at an observation time of 3 days to 0.78 at 2 weeks is almost significant. At observation times of 4 and 8 weeks $MAT = 0.75$. The decrease in MAT was so much greater on the control side than on the treated side that MADT was significant at an observation time of 2 weeks.

Adult animals

For the control side the regression curve for the activity value (A) of the individual sectors lacked a parabolic shape throughout. At time point 2.8 the curve showed a significant downward slope for the dorsal and fibular sectors and a tendency to a downward slope for the ventral sector. At this time point none of the sectors on the control side showed a significant A value.

For the treated side the regression curve for A lacked a significant parabolic shape throughout. At time point 2.8 the curve showed no significant

Fig 34 Adult animals Mean standardized growth difference value (MSGDT) in each experimental group at observation times of 3 days to 8 weeks

Study of the Absolute Growth Values

Growing animals (Fig 35)

On the control side MGT was 3.8 U at an observation time of 3 days, 0.9 at 2 weeks, 2.0 at 4 weeks and 3.5 at 8 weeks. On the treated side MGT was 13.1 U at 3 days, 4.8 at 2 weeks, 5.0 at 4 weeks and 2.8 at 8 weeks. On the control side a significantly lower MGT value was found in the animals observed at 2 weeks than in those observed at 3 days and an almost significantly higher MGT value in the animals from the combined groups observed at 4 and 8 weeks compared with those observed at 2 weeks.

On the treated side no significant difference in MGT was seen between the different experimental groups but the values showed a distinct tendency

Fig 35 Growing animals Mean growth value (MGT) and growth difference value (MGDT) in each experimental group at observation times of 3 days to 8 weeks
 ●—● MGT for treated tibia ○—○ MGT for control tibia □—□ MGDT

Fig 33 Growing animals Mean standardized growth difference value (MSGDT) in each experimental group at observation times of 3 days to 8 weeks

at time point 2.8 MAD was 0.6, which is an almost significant difference value

A study of the relations of the individual experimental groups showed that on the control side MAT was 0.4 at an observation time of 3 days, 0.05 at 2 weeks, 0 at 4 weeks and 0.08 at 8 weeks (Fig 32). The decrease between the observation times of 3 days and 2 weeks was not significant. On the treated side MAT was 0.5 at an observation time of 3 days, 0.9 at 2 weeks, 0.35 at 4 weeks and 0.43 at 8 weeks. The increase from 0.5 to 0.9 is not significant. The decrease from 0.9 to 0.35 is almost significant. There was a highly significant positive activity difference at an observation time of 2 weeks.

Studies of the Standardized Growth Difference

Growing animals (Fig 33)

At observation times of 3 days and 1 week almost significant positive MSGDT values were found and at 2 weeks, highly significant positive MSGDT values. An almost significant positive difference in MSGDT was found between the combined animal groups observed at 3 days, 1 week and 2 weeks compared with the groups observed at 4 and 8 weeks.

Adult animals (Fig 34)

Almost significant positive MSGDT values were found in the animal group observed at 1 week and highly significant at 2 weeks. The group observed at 2 weeks showed a significantly higher MSGDT than the group observed at 3 days and an almost significantly higher value than the group observed at 4 weeks.

Fig 37 Growing animals Mean resorption value (MRT) and resorption difference value (MRDT) in each experimental group at observation times of 3 days to 8 weeks
●—● MRT for treated tibia ○—○ MRT for control tibia, □—□ MRDT

during different periods of observation has been assessed. Their observations have been combined with studies of the morphology of the bone at the end of each observation period and from these findings conclusions have been drawn on the course of the periosteal bone growth.

In the present investigation this course has been studied by other methods as follows:

(1) Qualitative recording of the bone formation capacity of the periosteum some days before the angiographic examination was performed by determining the activity values. The development of the activity values during the whole period of observation (eight weeks) was studied by means of regression analysis.

(2) Quantitative recording of the bone formation was performed by measuring the thickness of the bone and osteoid tissue which had formed during the last days of each observation period. The large variation in the bone formation rate between different animals and different sectors was evened out by calculating the standardized growth difference. For this purpose the quantitative measurement value was converted to a qualitative unit.

(3) A recording was made of whether the sectors showed superficial resorption or not.

By studying these variables for the treated side, for the control side and for the difference between the treated and control sides, the development of the subperiosteal bone formation activity could be assessed both qualitatively and quantitatively.

Fig 36 Adult animals Mean growth value (MGT) and growth difference value (MGDT) in each experimental group at observation times of 3 days to 8 weeks
 ●—● MGT for treated tibia ○—○ MGT for control tibia □—□ MGDT

towards lower values at longer observation times. There was an almost significant MGDT between the treated and control side at observation times of 1 and 2 weeks. The highest MGDT was found at 3 days, but this value was not significantly increased. The value is largely accounted for by a high GD in 8 pairs of sectors in the three animals 125, 3 and 81.

Adult animals (Fig 36)

On the control side MGT was 0.6 U at an observation time of 3 days, 0.1 at 2 weeks, 0 at 4 weeks and 0.1 at 8 weeks. On the treated side this value was 1.1 U at 3 days, 7.6 at 2 weeks, 1.0 at 4 weeks and 0.7 at 8 weeks. The maximal MGT on the treated side and the maximal MGDT were found at an observation time of 2 weeks. At this time MGDT was almost significant.

Study of the Resorption Values (Fig 37)

A significantly positive MRT was found both on the treated side and on the control side at an observation time of 2 weeks. MRT was so much higher on the control side than on the treated side that at this observation time MRDT was almost significantly negative. At observation times of 3 days and 1, 4 and 8 weeks MRDT was not significant.

Discussion

In previous studies on the reaction of the periosteum after disturbances of the endosteal circulation (Rohlich 1941, Kuntscher 1957, Flatmark 1967, Trueta & Cavadias 1955, Richany *et al* 1965, Mital & Cohen 1966, Zucman *et al* 1968) the total amount of bone which has newly formed

than the absolute growth on the control side at 3 days (3.8 U) a significant absolute growth difference was found at 2 weeks.

The study of sectors undergoing resorption (MRT) showed that a significantly increased number of sectors were undergoing resorption at an observation time of 2 weeks both on the treated and control side. The resorption was so much greater on the control side that an almost significant negative resorption difference (MRDT) was found at 2 weeks. The analysis thus showed that the bone formation activity both on the treated and on the control side at an observation time of 2 weeks was distinctly lower than at 3 days. In growing animals the periosteum on the treated side thus seems to be activated to bone formation most strongly on the days immediately following reaming of the medullary cavity — no distinct maximum was recorded. The difference between the treated and the control sides was greatest at an observation time of 2 weeks. This rapid increase in the periosteal bone formation following medullary trauma corresponds well with the results of Tonna & Cronkite (1961). They studied the DNA synthesis in the osteogenic layer of the tubular bone after fracture and found that away from the fracture this began to increase 16 hours after the fracture and reached a maximum at 32 hours. In the present material a later phase in the bone formation was studied than in the material reported by Tonna & Cronkite.

At an observation time of 4 weeks a partial elimination of the activity difference, the standardized growth difference, the absolute growth difference and the resorption difference took place in the growing animals. At an observation time of 8 weeks a tendency was observed to more active bone formation on the control side than on the treated side.

Adult Animals

As in the growing animals the control side in the adult rabbits showed its maximal activity value (MAT) at an observation time of 3 days. In spite of this relatively high activity value only a very small absolute growth value (MGT) was found. The activity value on the control side then decreased and reached a minimum at 2–4 weeks. The activity value (MAT) and absolute growth value (MGT) on the treated side, the activity difference (MADT), the standardized growth difference (MSGDT) and the absolute growth difference (MGDT) all increased to a maximum at an observation time of about 2 weeks. As in the growing animals there seemed to be a partial elimination of the differences between the treated and control sides at 4 weeks. No compensatory phase with greater bone formation activity on the control side than on the treated side was observed in the adult animals.

In the growing animals all sectors were active both on the treated and the control side ($MAT \approx 1$) at an observation time of 3 days. Since all animals in this group were given tetracycline 1 day after the operation, these activity values actually reflect the situation about 1 day postoperatively. The high activity which was observed at that time on the control side may either reflect the normal bone formation activity of the animal or be a result of stimulation from the operation on the contralateral bone. The results obtained by Tonna & Cronkite (1961) appear to contradict the second possibility. On study of the cell proliferation in the periosteum after experimental fracture on the rat tibia, they found no stimulation of the cell division on the contralateral bone.

The high activity value on the control side meant that no activity difference occurred at an observation time of 3 days despite the fact that the activity value on the treated side was then maximal. At 3 days the absolute growth on the treated side (MGT) and the absolute growth difference (MGDT) showed their highest values. But at that time point the increase in MGDT was not significant since it referred to a relatively small number of sectors which showed a very high degree of growth. The standardized growth difference (MSGDT) was almost significantly increased, however, at an observation time of 3 days. This indicates that a difference existed between the growth on the treated side and on the control side at this time point even though this was not expressed in an activity difference or an absolute growth difference.

Compared with the animals observed at 3 days those observed at 2 weeks showed a lower activity value (MAT) and a lower absolute growth value (MGT) on the treated side. The absolute growth difference (MGDT) was also smaller at 2 weeks while the standardized growth difference (MSGDT) was not significantly changed. The activity difference (MADT), the standardized growth difference (MSGDT) and the absolute growth difference (MGDT) showed almost significantly positive values, however, at an observation time of 2 weeks. The high activity difference (MADT) which was found at that time point was due to a large reduction of the activity value (MAT) on the control side and the significant activity difference occurred despite the fact that the activity value on the treated side was lower than that at 3 days. Also for the occurrence of the significant positive absolute growth difference (MGDT) at an observation time of 2 weeks a significant reduction of the absolute growth (MGT) on the control side played a decisive role. Even though the absolute growth on the treated side at an observation time of 2 weeks was thus only slightly greater (4.8 U)

Fig. 38 Histological cross section of dorsal part of cortex observation time 2 weeks Growing animal 45 Stained osteocytic nuclei are present in the inner avascular part of the cortex

Shrinkage of the osteocytic nucleus was seen in bone tissue also on the control side and could not therefore be used as a sign of bone necrosis

In sections from animals observed at 3 days small scattered areas were observed in the inner and middle part of the cortex where the osteocytic lacunae lacked stainable material while in other parts of the cortex and in the surrounding soft tissues the nuclear staining was good No difference between the treated and the control side was observed however

Sections from animals observed at 1 week showed similar pictures to those from animals observed at 3 days

In sections from animals observed at 2 weeks scattered areas larger than on the control side were seen in the middle and inner parts of the cortex with practically no stainable osteocytic nuclei on the treated side These areas sometimes comprised more than one quarter of the surface area of the section In sections from one animal (45) the vessels in the middle and inner parts of the cortex showed no filling with Indian ink In these areas however several stained osteocytic nuclei were seen (Fig 38) In a few bone fragments which lay freely in the medullary cavity which completely lacked Indian ink filled vessels stained nuclei were observed in several osteocytic

Conclusion

In growing animals the bone formation activity on the treated side seemed to be greatest on the days immediately after reaming of the medullary cavity. This activity then decreased on the treated side so that at 2 weeks it was on the same level as that on the control side at 3 days. Since, however, the reduction of the bone formation activity was at the same time relatively greater on the control side there was still a significant difference between the treated and control sides at 2 weeks. At an observation time of 4 weeks the bone formation difference was almost eliminated and at 8 weeks there was a tendency to a negative difference.

In adult animals there was somewhat greater bone formation activity on the treated side than on the control side at an observation time of 3 days. This difference was maximal at about 2 weeks and was partly eliminated at 4 weeks.

STUDY OF THE HISTOLOGICAL SECTIONS

The histological picture in periosteal bone formation, the reconstruction of the cortex and the reformation of the structure of the medullary cavity after disturbances of the endosteal circulation have been described in detail previously in histological studies by Axhausen & Bergmann (1937), Ham & Harris (1956) and Branemark (1964) among others. In the present study the interest was therefore focused on the extent of the cortical necrosis. The appearance and stainability of the osteocytic nuclei were thus correlated to the Indian ink filling of the intracortical vessels in the area.

Method

The histological sections were stained with haematoxylin and eosin. The Indian ink filling of the intracortical vessels was assessed both on the histological and the angiographic sections prepared from the same paraffin embedded material.

Results

The osteocytic nuclei could best be studied on the histological cross sections. From each main experimental group at observation times of 3 days up to and including 4 weeks, sections were obtained from at least one animal in which the nuclear staining was satisfactory. The examination was therefore concentrated on these sections. In sections from several other animals, however, there was no nuclear staining at all either in the cortex or in the surrounding soft tissues.

Fig 38 Histological cross section of dorsal part of cortex observation time 2 weeks Growing animal 45 Stained osteocytic nuclei are present in the inner avascular part of the cortex

Shrinkage of the osteocytic nucleus was seen in bone tissue also on the control side and could not therefore be used as a sign of bone necrosis

In sections from animals observed at 3 days small scattered areas were observed in the inner and middle part of the cortex where the osteocytic lacunae lacked stainable material while in other parts of the cortex and in the surrounding soft tissues the nuclear staining was good No difference between the treated and the control side was observed however

Sections from animals observed at 1 week showed similar pictures to those from animals observed at 3 days

In sections from animals observed at 2 weeks scattered areas larger than on the control side were seen in the middle and inner parts of the cortex with practically no stainable osteocytic nuclei on the treated side These areas sometimes comprised more than one-quarter of the surface area of the section In sections from one animal (45) the vessels in the middle and inner parts of the cortex showed no filling with Indian ink In these areas however several stained osteocytic nuclei were seen (Fig 38) In a few bone fragments which lay freely in the medullary cavity which completely lacked Indian ink filled vessels stained nuclei were observed in several osteocytic

Fig 39 Hematoxylin eosin stained histological section observation time 2 weeks Growing animal 45 A fragment of cortical bone is lying freely in the medullary cavity In the surrounding area there are no newly formed blood vessels Stained nuclear material is seen in several of the osteocytic lacunae

lacunae (Fig 39) On fluorescence microscopy of the adjacent sections it was found that the bone fragments in the medullary cavity did not fluoresce

In sections from the treated side of animals observed at 4 weeks, scattered areas larger than those observed at 2 weeks were sometimes found in the middle and inner parts of the cortex where most of the osteocytic lacunae lacked stainable nuclei Corresponding angiography showed that some of the vessels here were filled with Indian ink In the cortex no sharp boundary was seen between the areas without and those with nuclear staining Nearest to the medullary cavity nucleus bearing osteocytic lacunae were observed where no Indian ink-filled vessels were seen

Discussion

Necrosis occurs in cortical bone a short time after the circulation to the cortex has been arrested (see literature reference p 21) The first histological sign of bone necrosis is shrinking of the osteocytic nucleus The necrotic nucleus becomes fragmented and nuclear material is carried away when the

fluid circulation to the area has been restored (Axhausen & Bergmann 1937) In certain cases this can take place only a few days after the occurrence of the necrosis but in other cases it can take a very long time The shrinking of the osteocytic nucleus in necrosis has been utilized by many investigators in the diagnosis of bone necrosis In the present material however the preparatory procedure gave rise as a rule to shrinkage of the osteocytic nucleus even in bone tissue which was not necrotic It was therefore not possible to determine the extent of the bone necrosis from the shrinkage of the osteocytic nuclei Instead an attempt at such determination was made by observing whether or not the osteocytic lacuna contained stainable nuclear material The absence of such material is usually a definite sign that the bone is necrotic (Axhausen & Bergmann 1937) but falsely empty osteocytic lacunae can occur in that the nucleus does not occupy the whole lacuna and that the section cuts through the lacuna without encountering the nucleus

In the specimens from this series of experiments there was no sharp borderline between nucleus bearing and non nucleus bearing regions of the cortex The latter regions visible at 2 weeks and increasing with observation time were observed especially on the treated side and there within the inner and middle part of the cortex Often however stainable nuclear material remained in the cortex even just adjacent to the medullary cavity at least up to 4 weeks after the reaming in the area where angiography showed that no vessels were filled with Indian ink

In loose bone fragments in the medullary cavity stainable nuclear material was observed 2 weeks after the reaming of the medullary cavity Corresponding fluorescence specimens showed that the bone fragments in the medullary cavity were not fluorescent which provided that no vessels were seen in the medullary cavity can be regarded as a sign that no fluid diffusion to the area had taken place two days before angiography

Thus stainability of osteocytic nuclei by no means constitutes a guarantee of the absence of necrosis even 4 weeks after operation

In the present material the extent of the bone necrosis could thus not be determined by the histological method used within 4 weeks after the operation This seems to be due to the fact that all necrotic nuclear material has not then been transported away from the osteocytic lacunae

It would seem therefore that the extent of the cortical damage after reaming of the medullary cavity can better be evaluated from the angiographic findings in specimens with a short observation time than from a study of the histological picture

Marrow Embolism as a Cause of Intracortical Circulation Block after Surgery of the Medullary Cavity

On reaming of the medullary cavity the intracortical circulation in the diaphysis is disturbed. This has been demonstrated by Indian ink angiography and is discussed on page 74. The blood vessels do not fill with Indian ink within large areas the extent of which varies greatly between different animals and between different sectors in the same animal. The reason for the deficient filling with Indian ink would therefore seem to be not only the elimination of the medullary circulation but also a simultaneous direct effect on the intracortical blood vessels. One possible cause of the intracortical circulatory disturbance is that the Haversian canals are occluded by medullary cavity contents which are squeezed into the canals when a surgical operation is performed in the medullary cavity.

In man fat emboli in the lungs often occur after fracture of the long tubular bones (for literature see Bergentz 1961). Kjerstell (1969) has shown that pulmonary fat emboli occurring in experimental femoral fractures in the dog originate in the traumatized fat tissue especially in the medullary cavity. Stained fat which is injected into the medullary cavity of a tubular bone gives rise to multiple emboli in the lungs when the bone is fractured (Glas *et al.* 1956) but also without fracture if the contents of the medullary cavity are mobilized by the introduction into it of a steel wire (Busch 1866). Bisgard & Baker (1940) claim that medullary fat enters the circulatory system for the reason that on such trauma the fat is released from the fat cell and becomes fluid that it accumulates under pressure on bleeding in the medullary cavity and that the open veins through the cortex do not collapse.

Bone marrow can thus leave the medullary cavity on intramedullary trauma but no investigations on the pathway of the marrow from the medullary cavity through the cortex and its possible influence on the intracortical circulation appear to have been reported previously. A series of experiments was thus carried out with the aim of answering the following questions

- 1 Do different degrees of medullary trauma give rise to different degrees of influence on the intracortical circulation?

Table 8 *Observation time number of animals and kind of treatment in the animal group used for study of fat emboli in the intracortical canals*

Observation time	No of animals	Treated tibiae		
		Suction	Reaming	Brushing
1 day	13	5	5	5
1 week	1		1	1
2 weeks	3		2	3
4 weeks	3		2	3

2 Are medullary emboli the cause of the disturbance of the intracortical circulation?

Material

The material comprised 27 growing and adult non pregnant rabbits of both sexes. Five of these animals (Table 9) which also served as controls were taken from the material presented in Table 1 namely 109 114 123 124 and 125 all of which belonged to the group studied at an observation time of 3 days. The sizes of the other animal groups, the lengths of the observation times and the kind of treatment are given in Table 8. Two animals died during the operation.

Methods

The anaesthesia and operation were performed as described in chapter 2.

The medullary cavity of the tibia was evacuated by one of the following three methods which gave rise to different pressure increases in the medullary cavity and partly as a result of these pressure increases was considered to be exposed to different degrees of medullary trauma (see p. 40): (1) suction (2) reaming (3) brushing.

Groups of animals were studied after observation times of 1 day and 1, 2 and 4 weeks (Table 8). The circulatory system was filled with Indian ink as described in chapter 2. In a deep frozen state the tibia was divided 2.5 and 7.5 cm from the tibio-talar joint. From each end of the middle part which was decalcified 1 cm was sawn off and used for Spalteholz preparations from which a drawing was made with the vascular front outlined according to the method described previously (see p. 29). On these drawings the percentage proportion of the cortical cross section with no Indian ink filling of the vascular system was calculated and named avascular cortex. From the intermediate part of the diaphysis 10-15 μ thick frozen sections were prepared. The sections were stained with Sudan 3 and haematoxylin and then mounted under a cover glass with Permount. Since the contents of the medullary cavity in the tibial diaphysis in the rabbit consist to a large part of fat, fat staining with Sudan 3 was used to indicate the presence of bone marrow.

From the five animals from the material presented in Table 1 bone material for frozen-sectioning was taken from the distal part of the diaphysis.

Table 9 *Mean number of marrow emboli per section from control and reamed tibias and the percentage of avascular cortex in the 5 animals from Table 1*

Animal no	Fat emboli per section		Percentage avascular cortex
	Control	Reamed	
109	0.3	2.0	19
114	0.3	3.7	26
123	0.7	20.0	61
124	0.0	2.3	9
125	0.7	8.0	31
Mean	0.5	7.2	

Results

Both tibiae from the five animals from Table 1 were studied three Sudan stained histological sections being studied from each tibia. In each section from the untreated control tibia an average of 0.5 fat emboli were found in intracortical vessels. The range of variation was 0-1 fat droplet per section. In sections from the reamed tibia an average of 7.2 fat droplets per section were found. The results are presented in Table 9. The table shows that the larger the amount of avascular cortex on the treated side the greater the number of fat droplets in the intracortical canals on that side.

Result of Differentiated Medullary Trauma

The percentage of avascular cortex 1 day after operation can be seen in Table 10. The table shows that reaming of the medullary cavity gave somewhat greater intracortical vascular damage than suction of the contents of the medullary cavity both in the distal and the proximal part of the diaphysis. The difference was not significant. Brushing out of the contents of the medullary cavity gave somewhat greater vascular damage than reaming or suction of the contents. The difference in this respect in the distal sections was significant at the 10 per cent level. A study of the Sudan stained sections showed that Sudan stained material was present in many Haversian canals in the areas of the cortex that lacked Indian ink-filled vessels (Color pl. 3 b c). As a rule the Sudan-stained material obliterated the entire Haversian canal, which then did not fill with Indian ink. In some cases only small fat droplets were found in the canals and Indian ink filled blood vessels passed these droplets. This was rather unusual however, and seemed to occur only in the outer part of the cortex. In these cases there were possibly two blood vessels in the same Haversian canal of which one was obliterated by fat. Haversian canals which were obliterated by fat were observed in

Table 10 Mean weights mean values and ranges of variation of avascular cortex for the tibiae of each group of 5 rabbits 1 day after suction reaming or brushing of the medullary cavity

P indicates the proximal section taken about 5.7 cm above the tibiotalar joint and D the distal section from about 2.7 cm above the same joint

		Suction	Reaming	Brushing
Percentage avascular cortex	{ P	44 (8-61)	56 (23-77)	64 (46-85)
	{ D	23 (6-34)	37 (14-54)	81 (64-93)
Mean weight kg		3.5 (3.3-3.9)	3.4 (3.1-3.9)	3.3 (3.1-3.7)

greatest abundance close to the medullary cavity. In animals in which anography preparations showed avascularity of the outer parts of the cortex Sudan stained material in Haversian canals was also observed however in the outer part of the cortex. In some preparations especially from the fibular part of the proximal area of the diaphysis a layer of marrow up to some mm thick was seen under the periosteum (Color pl 3 d)

In preparations from animals studied at observation times of 1 and 2 weeks the same pattern of fat in the Haversian canals was found as at an observation time of 1 day. At an observation time of 4 weeks some of the canals which contained Indian ink filled vessels were wider than those observed at 2 weeks. In some cases (Color pl 3 f) it was found that a Haversian canal had increased in calibre but that fat was still present in the canal at the side of an Indian ink filled blood vessel. Color pl 3 e shows how a cutter head is revascularizing an osteone whose canal in front of the cutter head is obliterated by fat.

Two of the animals died during brushing out of the medullary contents. They showed cyanosis, tachypnoea and tachycardia followed by bradycardia and died despite artificial respiration. At autopsy fat emboli were observed in Haversian canals of the treated tibia in many pulmonary vessels and in one renal vessel.

Discussion

The normal occurrence of fat in cortical bone was studied by Conklin *et al* (1956). They found only small quantities of lipids in osteocytes, osteocyte lacunae, canaliculi and in organic matrix and no fat droplets in the Haversian canals. Jones *et al* (1965) found in two patients with idiopathic avascular necrosis of the femoral head multiple fat droplets in the subchondral arterioles and in the capillaries in the necrotic bone. Karlstrom *et al* (1939) considered that one cause of avascular bone necrosis might be fat emboli in the intracortical blood vessels.

Mean	0.5	7.2	

Results

Both tibiae from the five animals from Table 1 were studied three Sudan stained histological sections being studied from each tibia. In each section from the untreated control tibia an average of 0.5 fat emboli were found in intracortical vessels. The range of variation was 0-1 fat droplet per section. In sections from the reamed tibia an average of 7.2 fat droplets per section were found. The results are presented in Table 9. The table shows that the larger the amount of avascular cortex on the treated side, the greater the number of fat droplets in the intracortical canals on that side.

Result of Differentiated Medullary Trauma

The percentage of avascular cortex 1 day after operation can be seen in Table 10. The table shows that reaming of the medullary cavity gave some what greater intracortical vascular damage than suction of the contents of the medullary cavity, both in the distal and the proximal part of the diaphysis. The difference was not significant. Brushing out of the contents of the medullary cavity gave somewhat greater vascular damage than reaming or suction of the contents. The difference in this respect in the distal sections was significant at the 10 per cent level. A study of the Sudan stained sections showed that Sudan stained material was present in many Haversian canals in the areas of the cortex that lacked Indian ink filled vessels (Color pl. 3 b c). As a rule the Sudan stained material obliterated the entire Haversian canal which then did not fill with Indian ink. In some cases only small fat droplets were found in the canals and Indian ink filled blood vessels passed these droplets. This was rather unusual however and seemed to occur only in the outer part of the cortex. In these cases there were possibly two blood vessels in the same Haversian canal of which one was obliterated by fat. Haversian canals which were obliterated by fat were observed in

Periosteal New Bone Formation Correlated to Endosteal Bone Removed, Cortical Vascular Damage and Subperiosteally Squeezed out Bone Marrow

There would seem to be several causative factors in periosteal new bone formation. Phemister (1930), Axhausen & Bergmann (1937) and Trueta (1963) consider that vascularly disturbed cortical bone causes local stimulation of periosteal osteogenic cells to new bone formation. Frost (1963) and Schenk (1967) claim that mechanical factors contribute to stimulation of the periosteum. Zucman et al. (1968) have shown that bone marrow which after an operation in the medullary cavity has become localized subperiosteally has a strong stimulatory effect on bone formation. The high osteogenetic potency of bone marrow has been demonstrated previously by several investigators including Urist & McLean (1952) and Burwell (1964) especially in connection with transplantation experiments.

The experimental methods used in the present study give prerequisites for new bone formation according to all of the above possibilities. In this chapter studies are described on the relationship between avascular bone or bone removed on reaming and the amount of new bone formed subperiosteally. The effect of subperiosteally localized bone marrow must however be evaluated indirectly.

For the studies of this relationship statistical methods of analysis were used.

Material

Twenty-four albino male and non-pregnant female growing rabbits were used. The ages of the animals were stated by the breeder to be between 14 and 18 weeks. They were divided into two groups, 1 and 2. Three animals were excluded from group 1 owing to fracture of the treated tibia and 4 animals were excluded from group 2 because of death in connection with the operation. After these exclusions group 1 comprised 7 animals and group 2, 10 animals. The mean weight of group 1 was 2340 g with a range of variation of 1600-2850 g and of group 2, 2470 g range 1700-2650 g.

This series of experiments showed that when the contents of the medullary cavity were removed by different methods, which gave rise to different degrees of medullary trauma varying degrees of vascular damage were obtained in the diaphyseal cortex lying outside. Suction of the contents of the medullary cavity gave the least vascular damage, while brushing out of the contents which caused the largest increase in the intramedullary pressure gave the greatest vascular damage. In those areas of the cortex in which the blood vessels did not fill with Indian ink at angiography, an abundance of Sudan stained droplets was often found in the Haversian canals. Sudan staining demonstrates the presence of fat and was used to indicate medullary tissue. In the areas in which almost every blood vessel filled with Indian ink, no or only a very small number of fat droplets were observed in the Haversian canals. In no section from control tibias which were not operated on was more than one Haversian canal obliterated by fat. The fat in the control tibias may have constituted emboli from the other treated tibia. On the histological sections it could not be determined whether the fat lay inside or outside the blood vessels. In preparations studied at an observation time of 4 weeks it was found that fat was still present in the Haversian canals and that it offered resistance to revascularization of the bone. Jones & Sakovich (1966) injected Lipiodol intravenously in the rabbit and observed Lipiodol in intracortical vessels during an observation time of 5 weeks. Cohen & Harris (1958) reported that the canals in cortical bone were wider nearer to the medullary cavity than peripherally under the periosteum. This could contribute to the fact that fat droplets on their way from the medullary cavity were stopped in the Haversian canals.

The rather high mean percentage of avascular cortex in the suctioned group may depend on the fact that high pressure was produced in the medullary cavity in some animals by the awl.

Conclusion

Intracortical emboli of the bone marrow are thus an important cause of intracortical vascular damage after medullary trauma. The contents of the medullary cavity can be squeezed out subperiosteally where they can be observed macroscopically as a haemorrhage.

Periosteal New Bone Formation Correlated to Endosteal Bone Removed, Cortical Vascular Damage and Subperiosteally Squeezed out Bone Marrow

There would seem to be several causative factors in periosteal new bone formation. Phemister (1930), Axhausen & Bergmann (1937) and Trueta (1963) consider that vascularly disturbed cortical bone causes local stimulation of periosteal osteogenic cells to new bone formation. Frost (1963) and Schenk (1967) claim that mechanical factors contribute to stimulation of the periosteum. Zucman *et al* (1968) have shown that bone marrow which after an operation in the medullary cavity has become localized subperiosteally has a strong stimulatory effect on bone formation. The high osteogenetic potency of bone marrow has been demonstrated previously by several investigators including Urist & McLean (1952) and Burwell (1964) especially in connection with transplantation experiments.

The experimental methods used in the present study give prerequisites for new bone formation according to all of the above possibilities. In this chapter studies are described on the relationship between avascular bone or bone removed on reaming and the amount of new bone formed subperiosteally. The effect of subperiosteally localized bone marrow must however be evaluated indirectly.

For the studies of this relationship statistical methods of analysis were used.

Material

Twenty four albino male and non pregnant female growing rabbits were used. The ages of the animals were stated by the breeder to be between 14 and 18 weeks. They were divided into two groups. 1 and 2. Three animals were excluded from group 1 owing to fracture of the treated tibia and 4 animals were excluded from group 2 because of death in connection with the operation. After these exclusions group 1 comprised 7 animals and group 2 10 animals. The mean weight of group 1 was 2340 g with a range of variation of 1600–2850 g and of group 2 2470 g range 1700–2650 g.

Methods

The anaesthesia and operation were performed as described in chapter 2. In group 1 the medullary cavity of the left tibia was evacuated by reaming and that of the right tibia by suction. In group 2 the medullary cavity of the left tibia was evacuated by brushing and that of the right tibia by suction. For both groups of animals the left tibia was called the treated tibia and the right the control tibia.

Bone Labelling

The animals were given approximately 50 mg tetracycline/kg body weight intraperitoneally on the day of operation and 5 days postoperatively.

Angiography

Angiography was performed as described in chapter 2, 7 days after the operation.

Preparation of the Sections for Analysis

After fixation in formalin the tibia was divided in the deep frozen state 2.5 cm above the tibiotalar joint. From the distal part of the proximal fragment three consecutive 12 cm long preparations were sawn. These were named from the distal end preparations *a*, *b* and *c*. Preparations *a* and *c* were embedded in methyl metacrylate and preparation *b* was decalcified and embedded in paraffin. From the distal and proximal parts of preparation *a* and from the distal part of preparation *c* $\frac{1}{2}$ mm thick slices were sawn and used for the preparation of ground sections for fluorescence microscopy. Further $\frac{1}{2}$ mm thick slices were then sawn from the same areas and used for Spalteholz preparations after removal of the methyl metacrylate with chloroform and decalcification of the specimen (See description of methods on p. 29). In this way three pairs of preparations were obtained. Each pair comprised one fluorescence preparation and one Spalteholz preparation taken from immediately adjacent bone. The pairs of preparations were named from the distal end: section 1 (SN1), section 2 (SN2) and section 3 (SN3). All three sections together were called SNT. SN1 was thus obtained from the distal part of preparation *a*, SN2 from the proximal part of preparation *a* and SN3 from the distal part of preparation *c*. The distance between SN1 and SN2 was about 11 mm and between SN2 and SN3 about 14 mm. From each section an image drawing was made in the way described on p. 28. Each image drawing was divided into four sectors and each sector into the areas AB, CD, CE and DE, after which the sizes of these areas were calculated. Area AB in sector 1 was called AB1 in sector 2 AB2 and so on.

Corresponding designations were used to denote the localization of the areas CD, CE and DE.

Analytical Methods

Between the values obtained for corresponding AB, CD, CE and DE areas on the treated and control sides the difference, the quotient and the difference between the logarithms were calculated. Analysis showed that difference calculation gave better correlation between the different sections than calculation of the quotient or of the difference between the logarithms. Difference calculation was therefore used throughout. The differences between the areas were denoted AB_d , CD_d , CE_d and DE_d . The values obtained were expressed in mm.

By for example the abbreviation CDd2SN3 is thus meant the difference between the sizes of areas CD on the treated and control sides in sector 2 in section 3

Calculations of the mean values of ABd CDd CE_d and DE_d were performed separately for the groups of animals treated by reaming (group 1) and by brushing (group 2) (Table 11). For groups 1 and 2 together each ABd value was correlated with the ABd values of all other sectors and certain formed sums of sectors (Table 12). By simple correlation analysis (Table 13) and by multiple regression analysis (Table 14) the ABd values were correlated with the corresponding values for CDd and DE_d.

Results

General Reaction of the Animals

In no case did wound infection or wound rupture occur. The mean change in weight during the experimental period of 1 week was -52 g in group 1 with a range of variation of +8 to -197 g and -34 g in group 2 with a range of variation of +310 to -300 g.

The animals bore weight normally on both legs a few days after the operation.

Mean Value Calculation of ABd CDd DE_d and DE_d (Table 11)

Calculation of the mean value of each sector in the three sections was performed separately for the reamed and brushed groups of animals. The mean ABd value was positive in all sectors in both the reamed and brushed groups and reached the almost significant level in sectors 1 and 2 in the reamed and in sector 2 in the brushed animals. The mean ABd value was somewhat higher throughout in the brushed animals than in the reamed but this difference did not reach the level of significance.

The mean CDd value was highly significantly raised in all sectors in the brushed animals. In the reamed animals the mean CDd value was highly significantly raised in sectors 1 and 3 and almost significantly raised in sectors 2 and 4.

On comparing the mean CDd values for the reamed and brushed animals it was found that these were higher throughout in the latter. The difference was almost significant in sectors 2 and 4 but not significant in the other sectors.

The mean CE_d value was highly significantly increased in all sectors in both the reamed and brushed animals. In sectors 2 and 4 in which most bone had been removed on reaming the mean CE_d value was somewhat higher in the reamed than in the brushed animals but in the other sectors somewhat lower. The difference between the reamed and brushed groups did not reach the level of significance.

Methods

The anaesthesia and operation were performed as described in chapter 2. In group 1 the medullary cavity of the left tibia was evacuated by reaming and that of the right tibia by suction. In group 2 the medullary cavity of the left tibia was evacuated by brushing and that of the right tibia by suction. For both groups of animals the left tibia was called the treated tibia and the right the control tibia.

Bone Labelling

The animals were given approximately 50 mg tetracycline/kg body weight intraperitoneally on the day of operation and 5 days postoperatively.

Angiography

Angiography was performed as described in chapter 2, 7 days after the operation.

Preparation of the Sections for Analysis

After fixation in formalin the tibia was divided in the deep frozen state 2.5 cm above the tibiotalar joint. From the distal part of the proximal fragment three consecutive 12 cm long preparations were sawn. These were named from the distal end preparations *a*, *b* and *c*. Preparations *a* and *c* were embedded in methyl metacrylate and preparation *b* was decalcified and embedded in paraffin. From the distal and proximal parts of preparation *a* and from the distal part of preparation *c* $\frac{1}{8}$ mm thick slices were sawn and used for the preparation of ground sections for fluorescence microscopy. Further $\frac{3}{8}$ mm thick slices were then sawn from the same areas and used for Spalteholz preparations after removal of the methyl metacrylate with chloroform and decalcification of the specimen (See description of methods on p. 29). In this way three pairs of preparations were obtained. Each pair comprised one fluorescence preparation and one Spalteholz preparation taken from immediately adjacent bone. The pairs of preparations were named from the distal end: section 1 (SN1), section 2 (SN2) and section 3 (SN3). All three sections together were called SNT. SN1 was thus obtained from the distal part of preparation *a*, SN2 from the proximal part of preparation *a* and SN3 from the distal part of preparation *c*. The distance between SN1 and SN2 was about 11 mm and between SN2 and SN3 about 14 mm. From each section an image drawing was made in the way described on p. 28. Each image drawing was divided into four sectors and each sector into the areas AB, CD, CE and DE, after which the sizes of these areas were calculated. Area AB in sector 1 was called AB1, in sector 2 AB2, and so on.

Corresponding designations were used to denote the localization of the areas CD, CE and DE.

The mean DEd value calculated in the reamed group of animals was highly significantly increased in sectors 2 and 4 and significantly increased in sector 1

Calculation of Correlation between ABd Values in Individual Sectors and Certain Sums of Sectors (Table 12)

The three sections in sector 1 were all highly significantly correlated to each other. In sector 2 section 3 differed greatly from the other two sections. In sector 3 section 2 differed greatly from section 3.

Sector 1 was the most homogeneous sector. The three sections in this sector were therefore suitable for use as reference sections. All three sections in sector 1 showed a weak correlation not only with ABd2SN3 which was very weakly correlated to all other sectors and sums of sectors but also with ABd3SN2 and ABd4SN2. ABd3SN2 and ABd4SN2 were highly significantly correlated with each other.

Almost all other sectors and sums of sectors were highly significantly or almost significantly correlated with each other.

Table 14 Regressors with coefficients significantly different from 0 and coefficients of determination (R^2) in an analysis with the sizes of ABd areas of different localizations as dependent variable and similarly localized CDd and DEd areas and also the type of operation as independent variables

Reamed = 1 Brushed = 0 n = 17		
Dependent variable	Regressors with significance according to multiple regression analysis	R^2
ΣABd in		
SN1	DEd (neg)	0.43
SN2	None	0.30
SN3	None	0.45
SN1 + 2	None	0.23
SN1 + 2 + 3	None	0.19
Sector 1	None	0.20
2	None	0.23
3	None	0.18
4	DEd (neg) Reamed (pos)	0.47

An almost significant positive correlation was found between ABd and the type of operation in sector 4. This correlation was found at DEd = 0 but not at those values for DEd which were obtained for the reamed animals. This almost significant correlation therefore lacked conclusive value.

Discussion

When the bone marrow in the rabbit tibia was removed by reaming or by brushing, greater intracortical vascular damage and somewhat greater periosteal new bone formation occurred than when the contents were removed by suction. With all three types of operation the medullary circulation was completely destroyed in the diaphysis of the bone. It would seem therefore that factors other than the loss of the medullary circulation should constitute the reason for the fact that somewhat more bone was formed subperiosteally on reaming or brushing than on suction.

In the studies described in chapter 4 it was shown that the intracortical vascular damage was due essentially to the fact that the intracortical blood vessels were obliterated by bone marrow which had been forced in as a result of the increase in pressure in the medullary cavity during the operation.

Correlation analysis and multiple regression analysis of the relationships between the ABd values and the corresponding CDd and DEd values showed that the amount of avascular bone in and the amount of bone removed on reaming from the underlying cortex had no apparent explanatory

2	0 39	-0 07
3	0 27	-0 24
4	0 05	-0 15

Correlation between Dependent Variable ABd and Corresponding Independent Variables CDd and DEd (Table 13)

A correlation analysis was performed both for the sum of all sectors in each individual section and for the sum of each individual sector with the same localization in all three sections

The correlation between the ABd values and the CDd values were positive throughout. An almost significant value was attained in section 3. This could be explained by the fact that one animal differed greatly from the rest and the significance was therefore of no explanatory value.

The correlations between the ABd and DEd values were positive throughout for individual sections, but negative throughout for individual sectors. The values did not reach the level of significance.

Regression Analysis with the Size of Differently Localized ABd Areas as Dependent Variable and the Size of Similarly Localized CDd and DEd Areas and also the Type of Operation as Independent Variables (Table 14)

The total explanatory value expressed as R was low throughout for the variables studied, the maximal value being 0 47.

On regression analysis an almost significant negative relationship was found between ABd and DEd in section 1 and in sector 4. On closer analysis of these relationships it was found, however, that they could be explained by the fact that the results from one animal differed greatly from the others. The almost significant correlation was therefore of no explanatory value.

In this material it could neither be demonstrated nor precluded that forced-out bone marrow was of importance for the increase in the ABd area in the other sectors

On comparison between animals treated by reaming and by brushing it was found that in the most reamed sectors 2 and 4 the reamed animals showed an almost significantly lower difference between the size of the CD areas on the treated and control sides than the "brushed" animals. In the other sectors no such difference was found.

This indicates that the reaming in itself gives no essential increase of the intracortical avascularity compared with operations which give the same degree of trauma in the medullary cavity.

tory value for the increase in the ABd area. This could be due either to the fact that this increase was not influenced by changes in the size of the CDd and DEd areas, or to the fact that an existing relationship was obscured by other, more dominating factors. It should also be emphasized that a true relationship might be difficult to demonstrate in view of the relatively small size of the material.

On analysis of the correlation between the ABd values in individual sectors, it was found that the increase in the ABd values in certain sectors differed considerably from that in the other sectors. This was true in particular for sector 2 (dorsal) in section 3, and to a smaller degree for sector 3 (fibular) and sector 4 (ventral) in section 2. It seems probable that the increase in the ABd values in these three sectors was highly influenced by other factors than those which produced an effect in the other sectors. The difference was most clearly evident when the three sectors in question were compared with the sections in sector 1 which were highly correlated with one another. The deviating reactionary pattern in these sections was found to be due to anatomical conditions. On dissection of this area it was found that the dorsal sector of section 3 was taken from the area immediately distal and dorsal to the outer opening of the primary nutrient foramen in the bone, above the fibulo-tibial synostosis. A fascia is attached ventral to the foramen and this should mean that marrow which was forced out through the foramen became localized dorsally on the tibia in the area from which the dorsal sector of section 3 was taken. The fibular and ventral sectors of section 2 were taken from the area immediately distal and ventro distal to the outer openings of the secondary nutrient foramen and emissary foramen. A fascia shields these openings here from the dorsal sector and this should mean that marrow forced out through these canals would have become localized fibularly and ventrally and may possibly have influenced the increase in the ABd values in these two sectors. The high correlation between these two latter sectors supports the assumption that they were influenced by the same dominating factors. The weak correlation between the dorsal sector in section 3 on the one hand and the fibular and ventral sectors in section 2 on the other supports the view that the ABd increase in these two groups of sectors was influenced by different dominating factors, probably by bone marrow which was forced out through different canals in the bone.

The analysis of the correlation between the three ABd values discussed above and the remaining ABd values thus supports the assumption that the increase in these three ABd values was influenced by forced out bone marrow. The results of the morphological studies reported in chapter 3 also support this view.

In this material it could neither be demonstrated nor precluded that forced out bone marrow was of importance for the increase in the ABd area in the other sectors

On comparison between animals treated by reaming and by brushing it was found that in the most reamed sectors 2 and 4 the reamed animals showed an almost significantly lower difference between the size of the CD areas on the treated and control sides than the brushed animals. In the other sectors no such difference was found.

This indicates that the reaming in itself gives no essential increase of the intracortical avascularity compared with operations which give the same degree of trauma in the medullary cavity.

The Effect of Reaming and Brushing of the Medullary Cavity on the Diaphysis of the Dog Femur

In chapter 3 a study was described of the effect of reaming of the medullary cavity and of brushing out of the bone marrow in the tibial diaphysis in the rabbit. In order to determine whether there were any differences in this respect between the rabbit and the dog corresponding investigations were also performed on the dog. The femur was used for these experiments.

Material

For the experiments 11 adult mongrel dogs were used (Table 15). The femur was chosen as the experimental bone since the tibia was used in these animals for studies of the healing pattern in compression osteosynthesis.

Methods

The dogs were anaesthetized with Nembutal[®] (Abbott for veterinary use) given intravenously until the cough reflex was eliminated. They were then intubated and ventilated with a mixture of oxygen and nitrous oxide.

After shaving the skin and washing with spirit the trochanter major was exposed through a lateral incision. The medullary cavity was opened with an awl medially to the trochanter major and was then widened 3–5 mm with hand driven reamers of the Kuntscher model (see Kuntscher 1962). The reaming was performed down to the distal metaphysis of the femur.

In two dogs the contents of the medullary cavity were removed with a bottle brush about 2 cm thick which was moved up and down in the cavity three times.

In order to label the newly formed bone Terramycin[®] (Pfizer) was injected intraperitoneally in a dose of 50 mg/kg body weight. The time points of the injections in relation to the operation can be seen in Table 15.

At the end of the experiment the animal was again anaesthetized and was given an intravenous injection of 500 U Heparin (Vitrum) per kg body weight. A catheter with an inner diameter of 1.5 mm was inserted in the external carotid artery in the direction towards the heart. Through this catheter a suspension consisting of 200 ml Pelikan Indian ink in 800 ml isotonic NaCl was infused under pressure with an ordinary Record syringe. After infusion of 100–200 ml the animal usually died. The infusion was then continued for a further few hours at a slow rate until 5 litres of the Indian ink mixture had been given. During the infusion the dog was kept in an

upright position so that the grains of Indian ink would be deposited in as many blood vessel branches as possible in the freely dependent legs

After the Indian ink infusion the femur was exarticulated at the hip joint and freed from soft tissues. After fixation for a few days in neutral 10% formalin the bone was frozen and in this state was divided the middle 5 cm being taken for examination. From each end of this 5 cm a 1 cm thick slice was sawn off and used for the preparation of histological sections and angiographic sections according to the Spalteholz method. A further 1 cm slice was then sawn off from each end of the specimen and these parts were embedded in methyl metacrylate and used for the preparation of fluorescence sections. The remaining part of the middle specimen was used in some cases for the preparation of Sudan-stained frozen sections.

The Spalteholz angiography sections were studied in a stereomicroscope and the fluorescence sections in an ordinary microscope under ultraviolet illumination as described in chapter 2.

Results after Reaming of the Medullary Cavity

General Reaction

As a rule the animals began to stand carefully on the treated leg a few days after the operation and were able to bear full weight on the leg about 1 week postoperatively. In no case was there any clinically manifest infection.

The Effect of Reaming and Brushing of the Medullary Cavity on the Diaphysis of the Dog Femur

In chapter 3 a study was described of the effect of reaming of the medullary cavity and of brushing out of the bone marrow in the tibial diaphysis in the rabbit. In order to determine whether there were any differences in this respect between the rabbit and the dog corresponding investigations were also performed on the dog. The femur was used for these experiments.

Material

For the experiments 11 adult mongrel dogs were used (Table 15). The femur was chosen as the experimental bone since the tibia was used in these animals for studies of the healing pattern in compression osteosynthesis.

Methods

The dogs were anaesthetized with Nembutal® (Abbott for veterinary use) given intravenously until the cough reflex was eliminated. They were then intubated and ventilated with a mixture of oxygen and nitrous oxide.

After shaving the skin and washing with spirit the trochanter major was exposed through a lateral incision. The medullary cavity was opened with an awl medially to the trochanter major and was then widened 3-5 mm with hand driven reamers of the Kuntscher model (see Kuntscher 1962). The reaming was performed down to the distal metaphysis of the femur.

In two dogs the contents of the medullary cavity were removed with a bottle brush about 2 cm thick which was moved up and down in the cavity three times.

In order to label the newly formed bone Terramycin® (Pfizer) was injected intraperitoneally in a dose of 50 mg/kg body weight. The time points of the injections in relation to the operation can be seen in Table 15.

At the end of the experiment the animal was again anaesthetized and was given an intravenous injection of 500 U Heparin (Vitrum) per kg body weight. A catheter with an inner diameter of 1.5 mm was inserted in the external carotid artery in the direction towards the heart. Through this catheter a suspension consisting of 200 ml Pelikan Indian ink in 800 ml isotonic NaCl was infused under pressure with an ordinary Record syringe. After infusion of 100-200 ml the animal usually died. The infusion was then continued for a further few hours at a slow rate until 5 litres of the Indian ink mixture had been given. During the infusion the dog was kept in an

blood vessels with thick walls. The bone trabeculae, as well as the endosteal surface of the cortex in the same area, were doubly labelled with an inner yellow fluorescent and an outer red fluorescent band. In this area the blood vessels and endosteal bone trabeculae had thus not been destroyed completely by the reaming. In the medullary cavity central to this region newly formed bone trabeculae were seen. Of these the trabeculae located nearest to the endosteum showed massive yellow fluorescence in the central regions and were covered with a red fluorescent band. Further inside the medullary cavity were other bone trabeculae the central parts of which showed massive red fluorescence.

Observation time 2 weeks

Labelling on days 6 and 12

Periosteum The periosteum was active and formed trabecular bone around almost the entire diaphysis. The newly formed bone was up to 2.2 mm thick. From labelling 1 a layer of newly formed bone with a maximal thickness of 400 μ was labelled. In the peripheral parts of the trabecular bone the trabeculae were narrow and surrounded by an abundance of perivascular soft tissue. In this area the trabeculae were homogeneously fluorescent from labelling 2. In the middle layer of the newly formed bone the trabeculae were wide, the perivascular soft tissue sparse and the blood vessels narrow. The central parts of the trabeculae were unlabelled while ring shaped labelling was seen around the vessels. In the inner layer of the trabecular bone the trabeculae were homogeneously fluorescent from labelling 1. In this part there were numerous narrow long cavities the walls of which were partly unlabelled by labelling 2 and in the unlabelled parts the walls were often rough—a sign of bone resorption.

Cortex In the cortex especially in its inner areas resorption cavities were observed the walls of which were partly covered by newly formed fluorescent bone and partly by narrow labelled areas indicating resorption. The newly formed bone was often seen on the peripheral wall.

Medullary cavity There was an abundance of newly formed trabecular bone in the medullary cavity. Many of the bone trabeculae adjacent to the endosteum showed superficial resorption.

Observation time 3 weeks

Labelling on days 7 and 19

Periosteum Superficial resorption was in progress around the entire diaphysis. From labelling 1 a band of even thickness around more than half of the diaphysis as well as occasional beams between the blood vessels

orescent band of newly formed bone, of almost even thickness. Outside this band, non-fluorescent bone and osteoid was seen. The largest amount of unstained bone was found in the tibial part, where trabecular bone up to $250\ \mu$ high had been formed.

Cortex In the middle part of the cortex numerous small resorption cavities which contained blood clots were seen. In some of these cavities, there were narrow, Indian ink filled blood vessels. All resorption cavities lacked fluorescence labelling of the walls.

Medullary cavity Newly formed bone trabeculae the central parts of which were fluorescent were found in the dorsal part of the medullary cavity adjacent to the endosteum. In other parts of the medullary cavity where newly formed blood vessels filled with Indian ink had invaded the medullary cavity from the cortex, bone fragments were found which had been released from the cortex by the reaming. The surfaces of the bone fragments were rough and many showed a thin fluorescent layer on the surface.

Observation time 13 days

Labelling on days 7 and 13

This dog died during the intravenous infusion of alizarin which in this experiment was used for labelling. 2. Angiography was therefore not performed.

Periosteum Active bone formation was observed around the entire diaphysis. The new bone consisted mainly of trabecular bone, but primary osteones were also found in some areas. From labelling 1 trabecular bone was labelled around a large part of the diaphysis but in some areas primary osteones or circumferential lamellae were labelled. The peripheral parts of the trabecular bone showed diffuse alizarin labelling but in the inner parts there were ring shaped labelled areas around the blood vessels. Adjacent to the surface of the original cortex several large cavities were found some of which continued into the original cortex.

Cortex In several areas adjacent to the medullary cavity resorption cavities were found, the rough surfaces of which showed a thin zone of alizarin labelling which was considered to be a sign of resorption. In other parts of the cortex osteones were found with an outer even fluorescent yellow Terramycin ring and an inner relatively thick even red ring of alizarin. These formations were osteones which were becoming closed. Some cavities showed yellow fluorescent bone deposits in one part of the wall and red resorption fluorescent layers in other parts.

Medullary cavity In the dorsal area broad bone trabeculae were found, communicating with the original cortex and between these there were some

blood vessels with thick walls. The bone trabeculae as well as the endosteal surface of the cortex in the same area were doubly labelled with an inner yellow fluorescent and an outer red fluorescent band. In this area the blood vessels and endosteal bone trabeculae had thus not been destroyed completely by the reaming. In the medullary cavity central to this region newly formed bone trabeculae were seen. Of these the trabeculae located nearest to the endosteum showed massive yellow fluorescence in the central regions and were covered with a red fluorescent band. Further inside the medullary cavity were other bone trabeculae the central parts of which showed massive red fluorescence.

Observation time 2 weeks

Labelling on days 6 and 12

Periosteum The periosteum was active and formed trabecular bone around almost the entire diaphysis. The newly formed bone was up to 2.2 mm thick. From labelling 1 a layer of newly formed bone with a maximal thickness of 400 μ was labelled. In the peripheral parts of the trabecular bone the trabeculae were narrow and surrounded by an abundance of perivascular soft tissue. In this area the trabeculae were homogeneously fluorescent from labelling 2. In the middle layer of the newly formed bone the trabeculae were wide, the perivascular soft tissue sparse and the blood vessels narrow. The central parts of the trabeculae were unlabelled while ring shaped labelling was seen around the vessels. In the inner layer of the trabecular bone the trabeculae were homogeneously fluorescent from labelling 1. In this part there were numerous narrow long cavities the walls of which were partly unlabelled by labelling 2 and in the unlabelled parts the walls were often rough—a sign of bone resorption.

Cortex In the cortex especially in its inner areas resorption cavities were observed the walls of which were partly covered by newly formed fluorescent bone and partly by narrow labelled areas indicating resorption. The newly formed bone was often seen on the peripheral wall.

Medullary cavity There was an abundance of newly formed trabecular bone in the medullary cavity. Many of the bone trabeculae adjacent to the endosteum showed superficial resorption.

Observation time 3 weeks

Labelling on days 7 and 19

Periosteum Superficial resorption was in progress around the entire diaphysis. From labelling 1 a band of even thickness around more than half of the diaphysis as well as occasional beams between the blood vessels

had become labelled. From labelling 2 ring shaped osteones which were becoming closed, were labelled. The periosteal reaction appeared to have been strongest over the lateral part of the bone corresponding to the area where the bone had been affected most by the reamer from the inside.

Cortex In the cortex there were rather few small resorption cavities, some of which showed active bone formation on the wall. Other cavities were unlabelled or exhibited a thin area of labelling indicating resorption. Three fairly large pear shaped resorption cavities were observed which from the periosteal surface were eroded into the original cortex under the area where considerable periosteal bone formation had taken place previously. No doubly labelled osteones were seen in the cortex.

Medullary cavity In the dorsal part doubly labelled endosteal bone and some doubly labelled newly formed bone trabeculae were seen. There was active bone formation on the bone trabeculae in towards the centre of the medullary cavity in several areas. Close to the endosteum many parts of the bone trabeculae were undergoing resorption, at the same time as other parts of the trabeculae showed active bone formation.

Observation time 4 weeks

Labelling on days 7 and 26

Periosteum Superficial resorption was taking place around the entire diaphysis. The periosteal reaction appeared to be strongest fibularly and tibio-ventrally. From labelling 1 the cross section showed fluorescent spicules between intermediate vessels and in some cases bridges over the vessels. On labelling 2 most of the primary osteones which had formed after the operation had become closed but in some of them a small fluorescent ring had formed close to the blood vessels. The bone which was fluorescent from labelling 1 also showed extensive superficial resorption. In those areas where the callus was thickest, long narrow resorption cavities were found adjacent and parallel to the original cortex.

Cortex Pronounced reconstruction was taking place in the entire cortex. In longitudinal sections several cutter heads were observed. A small number of doubly labelled osteones were seen in the outer and middle parts of the cortex. In the inner part of the cortex mainly single labelled osteones were found.

Medullary cavity In the central parts of the medullary cavity active trabecular bone formation was seen in towards a homogeneous almost structureless area which was invaded by narrow vessels. In the peripheral parts of the medullary cavity there was extensive resorption of trabecular bone but bone formation on the trabeculae was also seen.

Observation time 5 weeks

Labelling on days 7 and 33

Periosteum In the fibular part there was a prominence of newly formed bone. The periosteum over its peak was inactive but slight periosteal new lamellar bone formation was seen on the one side of the prominence. The prominence consisted of primary osteones in which some of the narrow blood vessel canals were surrounded by a narrow ring shaped fluorescent area while other osteones were completely closed at labelling 2.

Cortex In the cortex numerous small cavities were seen which were completely or partly lined with newly formed fluorescent bone.

Medullary cavity In the central part of the medullary cavity there was a structureless sparsely vascularized area. This was partly surrounded by a thin border of trabecular bone the bone trabeculae of which were directed inwards towards the structureless area. On the tips of the trabeculae which were directed in towards the centre an active deposition of bone was taking place while the peripheries of the trabeculae were undergoing resorption. In the remaining parts of the medullary cavity there were only widespread fragments of bone trabeculae undergoing resorption on which sporadic bone formation was also observed.

Observation time 6 weeks

Labelling on days 9 and 39

Periosteum Superficial resorption was taking place around the entire diaphysis. The fluorescence labelling showed that after the remaining primary osteones had formed but these had been largely reabsorbed.

Cortex Very active reconstruction was taking place in the cortex.

Medullary cavity The picture was similar to that from the animal observed at 5 weeks. The resorption of the bone trabeculae in the centre of the medullary cavity was so active that even the bone which was labelled by labelling 2 given 3 days before the angiography was undergoing extensive resorption.

Observation time 7 weeks

Labelling on days 10 and 47

Periosteum Superficial resorption was taking place around the whole diaphysis. Fluorescent ring-shaped structures around the blood vessels were seen from labelling 1. At the time of labelling 2 the first formed primary osteones were completely closed.

Cortex Very active reconstruction of the entire cortex was taking place but no doubly labelled osteones were observed in the inner part of the cortex.

Medullary cavity The preparation had about the same appearance as that observed at 6 weeks

Observation time 10 weeks

Labelling on days 10 and 56

Periosteum Periosteal bone formation with the development of lamellar bone was seen in a few areas, but otherwise extensive superficial resorption was taking place From labelling 1 there was fluorescence of the centres of the bone trabeculae which were formed after the reaming At labelling 2 the newly formed osteones were closed

Cortex Pronounced reconstruction of the entire cortex was taking place

Medullary cavity As in the preparations observed at 4, 5, 6 and 7 weeks there was a structureless area in the medullary cavity, penetrated by occasional blood vessels The structureless area bordered onto normal fatty bone marrow or the endosteal surface of the original cortex

Microangiographic Studies

Observation time 1 day

Periosteum The blood vessels in the periosteum were well filled with Indian ink, rather tortuous and appeared wider than normally especially in the fibular part of the preparation

Cortex Approximately one third of the inner part of the cortex was avascular The vascular damage was greatest in the fibular part where most bone had been removed from the endosteal surface on reaming The blood vessels in the outer part of the cortex were usually well filled The same Haversian canal often contained two blood vessels, of which one, which was narrower and massively filled with Indian ink, was considered to be an arteriole while the other, which was wider and often only lined with Indian ink, was considered to be a venule

Medullary cavity The medullary cavity was filled with a blood clot Bone appeared to have been removed from the entire endosteal surface by the reaming In the ventral and dorsal parts there were blood vessels which penetrated the whole cortex up to but not into the medullary cavity In front of the mouth of the blood vessel there was a minor extravasation of Indian ink into the medullary cavity

Observation time 7 days

Periosteum In the tibial sector of the preparation an intensive periosteal vascular reaction was observed The blood vessels were mutually parallel and ran at right angles to the surface of the cortex They were convoluted

and showed calibre variations. On several levels there were anastomoses between adjacent vessels. In the remaining parts of the periosteum there were tortuous well filled blood vessels which ran mainly parallel with the bone surface.

Cortex In the tibial sector of the bone about $\frac{1}{10}$ of the cortex was avascular. In the remaining parts the cortex was vascularized and the intracortical blood vessels were usually well filled with Indian ink.

Medullary cavity About one-quarter of the medullary cavity contained blood vessels. Blood vessels grew from the cortex within the ventral and dorsal sectors in the areas where the endosteum did not appear to have been damaged by the reamer. Several types of blood vessels were found in the medullary cavity. Nearest to the endosteum a small number of anastomosing vessels of even calibre and up to $200\ \mu$ wide which were lined with grains of Indian ink were seen. Central to these were blood vessels about $40\ \mu$ wide of even calibre and lined with Indian ink which anastomosed abundantly. In the area bordering on the non revascularized part of the medullary cavity there were convoluted vessels about $5\text{--}40\ \mu$ wide and massively filled with Indian ink of similar appearance to those vessels observed in the rabbit at an early phase of revascularization of the medullary cavity and subperiosteal haematomas (see p. 69).

Observation time 2 weeks

Periosteum There was a very strong vascular reaction around almost the entire diaphysis. The blood vessels in the up to 2 mm thick vascular layer ran mainly perpendicular to the surface of the cortex and showed numerous mutual anastomoses. In the outermost part of the vascular layer the blood vessels were convoluted and varied in calibre. In the middle part of the layer the vessels were usually of equal calibre about $20\ \mu$ wide and straight. Nearest to the original cortex in the areas where the thickest periosteal vascular reaction occurred there were blood vessels of equal calibre about $100\ \mu$ wide lined with Indian ink. These vessels ran mainly parallel with the surface of the original cortex. They were of the same type as were observed during resorption in periosteal and endosteal callus in the rabbit.

Cortex About half of the cortical cross section area was avascular. In some areas the entire cross section was avascular but in the dorsal sector the cortex was completely vascularized. Some of the blood vessel canals in the vascularized part of the cortex were considerably wider than in the non vascularized part. The canals often contained two blood vessels. In longitudinal sections loops of blood vessels leading to "cutter heads" and to broom shaped vascular proliferations were observed.

Medullary cavity Approximately half of the medullary cavity was revas-

Medullary cavity The preparation had about the same appearance as that observed at 6 weeks

Observation time 10 weeks

Labelling on days 10 and 56

Periosteum Periosteal bone formation with the development of lamellar bone was seen in a few areas, but otherwise extensive superficial resorption was taking place. From labelling 1 there was fluorescence of the centres of the bone trabeculae which were formed after the reaming. At labelling 2 the newly formed osteones were closed.

Cortex Pronounced reconstruction of the entire cortex was taking place.

Medullary cavity As in the preparations observed at 4, 5, 6 and 7 weeks there was a structureless area in the medullary cavity, penetrated by occasional blood vessels. The structureless area bordered onto normal fatty bone marrow or the endosteal surface of the original cortex.

Microangiographic Studies

Observation time 1 day

Periosteum The blood vessels in the periosteum were well filled with Indian ink, rather tortuous and appeared wider than normally, especially in the fibular part of the preparation.

Cortex Approximately one third of the inner part of the cortex was avascular. The vascular damage was greatest in the fibular part where most bone had been removed from the endosteal surface on reaming. The blood vessels in the outer part of the cortex were usually well filled. The same Haversian canal often contained two blood vessels of which one which was narrower and massively filled with Indian ink was considered to be an arteriole, while the other which was wider and often only lined with Indian ink was considered to be a venule.

Medullary cavity The medullary cavity was filled with a blood clot. Bone appeared to have been removed from the entire endosteal surface by the reaming. In the ventral and dorsal parts there were blood vessels which penetrated the whole cortex up to but not into the medullary cavity. In front of the mouth of the blood vessel there was a minor extravasation of Indian ink into the medullary cavity.

Observation time 7 days

Periosteum In the tibial sector of the preparation an intensive periosteal vascular reaction was observed. The blood vessels were mutually parallel and ran at right angles to the surface of the cortex. They were convoluted

Medullary cavity The medullary cavity was completely revascularized. Adjacent to the endosteum the vascular structure was as in normal bone marrow and inside this the same types of vessels as described at an observation time of 4 weeks were seen.

Observation time 6 weeks

Periosteum No periosteal vascular reaction was observed.

Cortex Active reconstruction was taking place in the cortex which was almost completely vascularized.

Medullary cavity The medullary cavity was revascularized. The angiographic picture was similar to that at an observation time of 5 weeks.

Observation time 10 weeks

Periosteum No definite periosteal vascular reaction was observed.

Cortex The entire cortex was vascularized. Pronounced reconstruction of the whole cortex was taking place and several vessel loops in cutter heads were seen.

Medullary cavity The medullary cavity was revascularized. In the peripheral parts of the medullary cavity the vascular structure was normal. More centrally there were fragments of bone trabeculae which lay in close contact with blood vessels up to 200 μ wide and lined with grains of Indian ink. In the central part of the medullary cavity there was a structureless area criss-crossed with vessels of the previously described type. A normal vascular structure was seen in some areas in direct contact with the homogeneous central region.

Studies of Histological Azan stained Sections

The histological studies were concentrated to the central area of the medullary cavity in animals with an observation time of more than 3 weeks. On the fluorescence microscopic and angiographic preparations an almost homogeneous area containing a sparse number of relatively narrow blood vessels was seen at this location.

Azan stained histological sections showed that the structureless area consisted of densely situated essentially parallel collagen fibre in which occasional cells, cell aggregations and blood vessels were interspersed. Between this connective tissue and the surrounding bone trabeculae there was a layer of cells with large nuclei. Collagen fibres ran from the bone trabeculae into the fibrous tissue. In other areas at an observation time of more than 5 weeks practically normal bone marrow or endosteal surface of the cortex bordered directly on to the fibrous tissue without any intervening layer of cells (Color pl. 2 b). At an observation time of 10 weeks the active bone formation at the border to the fibrous scar tissue had stopped.

cularized The same types of blood vessels were seen as in preparations observed at 1 week

Observation time 3 weeks

Periosteum The blood vessels in the periosteum were tortuous and dilated

Cortex About half of the fibular sector of the cortex was avascular In some preparations blood vessels had grown through the cortex into the medullary cavity even in areas where the reamer had removed bone from the endosteal surface

Medullary cavity The medullary cavity was almost completely revascularized Nearest to the endosteum there was a sparse number of the approximately $150\ \mu$ wide blood vessels which were described in preparations observed at 1 week In front of these, vessels of similar appearance but about 40μ wide were seen Central to these vessels on the border with non revascularized parts of the medullary cavity, anastomosing vessels were seen which were massively filled with Indian ink and which gave an impression of greater maturity than the blood vessels seen in corresponding areas in the animal observed at 1 week in that they were of more equal calibre and less tortuous

Observation time 4 weeks

Periosteum Dilated and tortuous periosteal vessels were observed in the fibular sector which was most affected by the reamer In other parts there was no definite increased vascular reaction

Cortex The cortex was almost completely vascularized In longitudinal sections vascular components of many cutter heads were observed

Medullary cavity The medullary cavity was completely revascularized In the peripheral parts there were large blood vessels up to $200\ \mu$ wide In the middle layer blood vessels about $40\ \mu$ wide were seen In the centre of the medullary cavity there was an almost structureless area which was sparsely invaded by fairly straight blood vessels about $20\ \mu$ wide and massively filled with Indian ink as well as sparsely anastomosing vessels about $30\ \mu$ wide and lined with Indian ink

Observation time 5 weeks

Periosteum In the lateral sector there was a moderate number of dilated periosteal vessels Otherwise no vascular reaction was observed

Cortex The cortex was almost completely vascularized The intracortical blood vessels appeared narrower and of more equal calibre than the vessels in preparations from animals at shorter observation times

Medullary cavity The medullary cavity was completely revascularized. Adjacent to the endosteum the vascular structure was as in normal bone marrow and inside this the same types of vessels as described at an observation time of 4 weeks were seen.

Observation time 6 weeks

Periosteum No periosteal vascular reaction was observed.

Cortex Active reconstruction was taking place in the cortex which was almost completely vascularized.

Medullary cavity The medullary cavity was revascularized. The angiographic picture was similar to that at an observation time of 5 weeks.

Observation time 10 weeks

Periosteum No definite periosteal vascular reaction was observed.

Cortex The entire cortex was vascularized. Pronounced reconstruction of the whole cortex was taking place and several vessel loops in "cutter heads" were seen.

Medullary cavity The medullary cavity was revascularized. In the peripheral parts of the medullary cavity the vascular structure was normal. More centrally there were fragments of bone trabeculae which lay in close contact with blood vessels up to 200 μ wide and lined with grains of Indian ink. In the central part of the medullary cavity there was a structureless area crossed with vessels of the previously described type. Observation time 4 weeks

Periosteum Dilated and tortuous periosteal vessels were observed in the fibular sector which was most affected by the reamer In other parts there was no definite, increased vascular reaction

Cortex The cortex was almost completely vascularized In longitudinal sections vascular components of many cutter heads were observed

Medullary cavity The medullary cavity was completely revascularized In the peripheral parts there were large blood vessels up to $200\ \mu$ wide In the middle layer blood vessels about $40\ \mu$ wide were seen In the centre of the medullary cavity there was an almost structureless area which was sparsely invaded by fairly straight blood vessels about $20\ \mu$ wide and massively filled with Indian ink as well as sparsely anastomosing vessels about $30\ \mu$ wide and lined with Indian ink

Observation time 5 weeks

Periosteum In the lateral sector there was a moderate number of dilated periosteal vessels Otherwise no vascular reaction was observed

Cortex The cortex was almost completely vascularized The intracortical blood vessels appeared narrower and of more equal calibre than the vessels in preparations from animals at shorter observation times

the contents of the medullary cavity were removed with a brush about 20 fat droplets were observed in every section. Many of the canals in the cortex in this femur were completely obliterated by fat.

Summary and Discussion

Periosteum After reaming of the medullary cavity the periosteal structures reacted in all animals. The blood vessels increased in calibre, became more tortuous and were filled massively with Indian ink on angiography. Vessels which ran perpendicular to the surface of the cortex were seen at observation times of 1 and 2 weeks. The vascular reaction began to decline at 4 weeks and appeared to be greatest and to persist longest in the area where the cortex had been most affected by the reaming from the inside.

The periosteal bone formation was very active throughout. In all animals primary osteones or trabecular bone were newly formed during the first few weeks postoperatively. The most abundant new bone formation appeared to take place in those parts of the cortex where most bone had been removed from the endosteal surface by the reaming. In these areas the vascular damage in the underlying cortex seemed to be greatest. Subsequently there was very rapid resorption of most of the newly formed bone. The bone resorption was most pronounced between 2 and 8 weeks postoperatively. At an observation time of 10 weeks some tendency to formation of lamellar bone was noted. The Terramycin labelling showed that about 1 week after the reaming mineralized bone beams were formed between the blood vessels and in some cases bridges over the vessels. The so-formed primary osteones closed successively during the following 2-3 weeks.

Cortex The extent of the intracortical vascular damage varied. The greatest damage to the vascular system was observed after brushing out of the bone marrow when about two-thirds of the cortex was seen to lack Indian ink filled vessels at subsequent angiography. In one animal about one third of the cortex became avascular after the reaming. The reason for the avascularity is at least in part that the contents of the medullary cavity are squeezed or embolized into the Haversian canals and occlude them. The cortex appeared to become revascularized fairly quickly, however. On preparations from animals studied 4 weeks or longer postoperatively the cortex was almost completely vascularized. The revascularization took place with the aid of cutter heads but a broom like vascular reaction which gave larger resorption cavities in the cortex was also observed. In some cases resorption cavities had formed also in the subperiosteal part of the original cortex. This occurred where there was a very strong periosteal reaction. It was probably due to the fact that the blood vessels in the outer part of the cortex had also been damaged. The rebuilding of the cortex as reflected in the

Results after Brushing out of the Medullary Content

Microangiographic Studies

Observation time 1 day

Periosteum The periosteal blood vessels were somewhat narrower and less tortuous than the vessels in preparations from the left femur, which had been reamed

Cortex About $1/10$ of the inner part of the cortex was avascular. Many Indian ink filled vessels, especially in the dorsal and ventral parts, penetrated the entire cortex to the medullary cavity. A little extravasation of Indian ink was seen in the medullary cavity just in front of their opening.

Medullary cavity The medullary cavity was filled with a blood clot and no Indian ink-filled vessels were observed.

Observation time 2 days

Periosteum The periosteal vascular reaction was stronger than in preparations observed at 1 day. The blood vessels were tortuous and massively filled with Indian ink.

Cortex About two-thirds of the cortex was avascular. In the dorsal sector blood vessels were seen to penetrate the entire cortex as far as the medullary cavity.

Medullary cavity The medullary cavity was filled with a blood clot and no Indian ink-filled vessels were observed.

Histological Results after Reaming and Brushing

Studies of Fat stained Histological Frozen Sections

Observation time 1 day

In every cross-sectional preparation from the right femur where the content of the medullary cavity was removed with a bottle brush there were about 10 fat droplets, which obliterated Haversian canals in the inner part of the cortex. In preparations from the left femur, where the contents of the medullary cavity were removed by reaming approximately the same number of fat droplets were seen localized in the same way.

Observation time 2 days

In preparations from the control femur which was not operated on occasional fat droplets were observed obliterating Haversian canals in the inner part of the cortex. In five cross sectional preparations a total of only three fat droplets was seen. In preparations from the other femur from which

massive than around the tibia but this should not have influenced the results essentially

The periosteal reaction appeared to be stronger in adult dogs than in adult rabbits. In all dogs woven bone in primary osteons or trabecular bone formed subperiosteally which is rather uncommon in adult rabbits. The resorption of the newly formed bone also appeared to take place considerably more intensively in the dog than in the rabbit.

The intracortical vascular damage in the dog as also in the rabbit varied greatly. It is reasonable to assume that the degree of intracortical vascular damage in the dog was dependent to a large extent on the pressure increase which occurred in the medullary cavity during the operation which was found to be the case in the rabbit (see chapter 2). Thus an experiment with brushing out of the medullary cavity in the dog when a thick bottle brush was used gave rise to considerable vascular damage in the cortex. The reamers used in dogs and which were hand-driven were so formed that they probably gave only a relatively small pressure increase in the medullary cavity. The reamers used in the rabbit experiments on the other hand resembled more the mechanically driven reamers of the Kuntscher or AO type which are used in the clinic (See Muller *et al.* 1965). Revascularization of the cortex appeared to take place more rapidly in the dog than in the rabbit but this opinion is uncertain since the primary vascular damage varied greatly. The rebuilding of the cortex with the formation of secondary osteons appeared to be more intensive in the dog than in the rabbit.

Reaming of the medullary cavity did not always result in complete destruction of the blood vessels in the diaphyseal medullary cavity in the dog which always seemed to occur in the rabbit. This is probably due to the fact that the dog has endosteal bone trabeculae which protect the vessels nearest to the endosteum especially in the dorsal part of the medullary cavity while in the rabbit the endosteal surface in the diaphysis is quite smooth. The medullary cavity becomes revascularized very rapidly in the adult dog and bone formation starts earlier than in the adult rabbit. The same types of blood vessel were observed in the medullary cavity in both animals during revascularization. In the central parts of the medullary cavity in the dog a fibrous cicatricial tissue sparsely interspersed by blood vessels was often observed. This tissue was also seen in the rabbit but was less prominent there.

number of secondary osteones increased continuously throughout the experimental period up to 10 weeks after the operation. Practically the entire cortex including the subperiosteal part, was reconstructed. In primarily avascular areas of the cortex the new bone formation in resorption cavities appeared to commence about 10 days after the operation.

Medullary cavity. In one case undamaged vessels were seen in the dorsal part of the medullary cavity after the reaming. This seems to be due to the fact that during the reaming the vessels were protected by endosteal bone trabeculae which were not removed by the reamer. Revascularization of the medullary cavity began quickly, usually first from blood vessels in the dorsal part of the cavity. The first vessels to invade the medullary cavity were abundantly anastomosing vessels of varying calibre and massively filled with Indian ink, of the type observed in the rabbit medullary cavity in the early revascularization phase. Kookenberg (1963) classified this type of blood vessel as type 3 (see p. 76). These vessels later underwent a change to relatively narrow abundantly anastomosing vessels of more equal calibre around which trabecular bone was formed. Newly formed bone in the medullary cavity became fluorescent from Terramycin which was given 5 days after the operation. Resorption of the newly formed bone trabeculae adjacent to the endosteum was observed 1 week postoperatively. These trabeculae were then surrounded by vessels of large calibre which appeared to become transformed to normal sinusoids when the bone trabeculae had become resorbed. After an observation time of 2 weeks the type of immature vessel which was first seen in the medullary cavity was no longer present there and instead more mature vessels were seen close to the central as yet not revascularized part of the medullary cavity. After an observation time of 4 weeks an area of connective tissue interspersed by sparsely anastomosing narrow vessels of which many were massively filled with Indian ink was observed mainly localized to the central part of the medullary cavity. On preparations studied after a long observation time this fibrotic area seemed to be inactive. It bordered directly on the normal medullary tissue or to the endosteal surface of the original cortex. Whether the fibrous area would remain as a scar or whether it would be rebuilt later cannot be decided. The absence of cells between the fibrous area and normal marrow tissue or cortex supports the former alternative however.

Comparison between the Reaction in the Rabbit and Dog on Reaming of the Medullary Cavity

In the rabbit the investigation was performed on the tibia and in the dog on the femur. The musculature around the femur is considerably more

On suction reaming or brushing of the medullary cavity the medullary blood vessels in the diaphysis of the bone were destroyed. This was especially effective in the rabbit. Furthermore, on reaming bone was removed from the endosteal surface of the diaphysis. On destruction of the medullary vessels the cortex was deprived of that part of its circulation which came from the medullary cavity. When this destruction resulted from reaming between 10 and 60% of the cortical cross sectional area became avascular. An approximately equal degree of avascularity occurred in the distal and proximal parts of the diaphysis. In a few isolated sectors in some animals, however, practically all intracortical vessels were filled with Indian ink. Suction as a rule resulted in considerably less cortical avascularity than reaming or brushing. The loss of the medullary circulation is thus not an essential cause of the cortical avascularity after operations in the medullary cavity and there are other more important factors which are discussed below.

Friction heat produced by the reaming is of no or very little importance as a cortex-damaging factor under the given experimental conditions. On the other hand, the increase in pressure which can occur during operations in the medullary cavity can be of great importance. Pressure increases far exceeding the systolic blood pressure are produced very easily and one result is that bone marrow is forced into the intracortical canals and obstructs the blood circulation there. It is also conceivable that pressure increases may result in tearing of the intracortical vessels so that the circulation is directly occluded or with less damage in the occurrence of secondary thrombosis.

A good correlation was found between extensive cortical avascularity, a large number of intracortical marrow emboli and a high intramedullary pressure produced by incautious reaming or brushing in the medullary cavity. On the other hand, only very slight cortical avascularity and few intracortical emboli were found, for example, on careful reaming or suction in the medullary cavity.

These results thus indicate that if the medullary circulation is occluded without the intracortical vessels being obstructed by marrow or being directly damaged, the periosteal vessels can maintain the circulation in almost the whole of the intracortical vascular bed. It is improbable, however, that at an early stage after the operation the intracortical circulation is sufficient to nourish all bone tissue, especially not in the cortex nearest to the medullary cavity. The incomplete filling of the functioning intracortical blood vessels at observation times of less than 24 hours support this assumption.

My conclusions on the ability of the periosteal vessels to take over the intracortical nutrition when the medullary vessels have been destroyed thus

General Discussion and Summary

Danis (1947) stated that in his experience diaphyseal fractures stably fixed with compression plate osteosynthesis heal without roentgenologically visible periosteal callus. Several authors have since found that the amount of periosteal callus is related to the degree of stability. The AO group aim also with their stable osteosyntheses at obtaining callus-free bone healing.

On healing of femoral fractures stably fixed by intramedullary nailing after reaming of the medullary cavity, a large amount of periosteal callus is often formed, however, even if judging by clinical and roentgenological signs, the osteosynthesis remains stable. On intramedullary nailing there is therefore some additional factor which stimulates the periosteal new bone formation.

In order to study this problem under reliably stable conditions different surgical procedures (brushing suction, reaming) were carried out in the medullary cavity of the tibia in growing and adult rabbits and of the femur in adult dogs without the leg being fractured.

The traumatization of the bone and its circulation which was produced by the operation in the medullary cavity induced characteristic reactions in the periosteum and cortex and in the medullary cavity itself. Bone was formed subperiosteally among other places and the bone which was newly formed after the operation was labelled with tetracyclin, the ultraviolet fluorescence of which was studied microscopically in plastic-embedded ground sections. The microcirculation in the cortex was studied by angiography at the end of the experimental period and preparations treated according to the Spalteholz technique were examined by stereomicroscopy. The extent of the intracortical vascular damage and the amount of periosteal newly formed bone were quantitated in cross-sections. The development of the periosteal bone formation activity was evaluated by recording whether the surfaces of the bone sections were fluorescent or not and by measuring the thickness of the bone and osteoid which were formed on the days preceding the angiographic examination. The pressure conditions in the medullary cavity were recorded on reaming and brushing and the temperature increase on reaming. Conventionally stained histological preparations and Sudan-stained frozen sections of bone were studied.

The methods of recording and measurement were found on testing to have good reliability.

nk were found during the formation of circumferential lamellae. Several layers of similar vessels developed during the formation of primary osteones. Relatively straight, frequently anastomosing vessels at right angles to the cortex and often of considerable length preceded the formation of trabecular bone. The vascular reaction was observed in the periosteum as long as the new bone formation or bone destruction there was increased, but during the process of maturation of the bone the vessels became narrower and straighter.

The periosteal newly formed bone could be either lamellar or woven bone. Lamellar bone which was present in circumferential lamellae and in some primary osteones was not reconstructed during the course of maturation. In woven bone which was found in certain primary osteones and especially abundantly in trabecular bone, resorption cavities were sometimes observed. These cavities gave the impression of migrating in a central direction towards the medullary cavity. Subperiosteally formed woven bone was not observed during the normal periosteal growth in rabbits of the ages studied. This could therefore be regarded as pathological bone formation which only occurred during the first 2-4 weeks after the operation. In some cases after partial superficial resorption it was later covered by deposition of lamellar bone. The perivascular spaces between the primary trabeculae of woven bone decreased by the formation of lamellar bone on the trabeculae. In this way the primary osteones closed during the course of about 4 weeks.

The periosteal bone formation activity was of varying intensity at different times after reaming of the medullary cavity. In the rabbit the activity in the treated tibia which in growing animals was maximal a few days after the operation had decreased at an observation time of 2 weeks to almost the same level as was noted at 4 and 8 weeks. Also on the control side the periosteal bone formation activity varied. A few days postoperatively it was high; it decreased to a minimum at 2 weeks and then again increased. The reduction of the activity in the control tibia meant that the difference in the bone formation activity between the treated and control tibias was greatest at an observation time of 2 weeks despite the relatively low activity observed at that time point in the treated tibias. Owing to a subsequent increase in the activity in the control tibia there was a partial equilibration with the treated tibia at an observation time of 4 weeks. Extensive superficial resorption at 2 weeks, most pronounced in the control tibia but also considerable on the treated side, also indicated that the activation to periosteal bone formation which was induced by the operation in the medullary cavity had almost ceased 2 weeks postoperatively. In adult rabbits in which there was no appreciable spontaneous periosteal bone formation the formation of bone on the treated side was activated more slowly than in the

differ somewhat from those of many previous investigators Macnab (1958) McAuley (1958) and Gustilo *et al* (1964) thus considered that the periosteal vessels were unable to supply any part of the cortex, and Trueta & Caldias (1964) claimed that only the outer third of the cortex could be supplied by periosteal vessels de Marneffe (1951, 1953) considered that in the proximal part of the tibial diaphysis in the rabbit the periosteal vessels could only supply the outer part of the cortex but in the distal part of the diaphysis the whole cortex Gothman (1961) and Rhinelander & Baragry (1962) found that during the first days up to one week after destruction of the medullary vessels the intracortical vessels were filled very incompletely from periosteal vessels (according to the latter authors due to the fact that normally many intracortical vessels are resting) but that the periosteal vessels were then able to take over the circulation in the cortex

The differences in the conclusions may be due to the fact that these investigators used Micropack as perfusion medium which seems to have difficulty in passing through the vessels in the subperiosteal bone before they have increased in calibre about one week after the operation They may also be due to the fact that a pressure increase was produced in the medullary cavity in their experiments resulting in marrow emboli in the intracortical vessels but that sufficient consideration was not taken of these factors

On increase in pressure in the medullary cavity bone marrow can be forced through canals in the cortex and deposited subperiosteally or transported further into the venous system to be filtered mainly in the lungs The transport of bone marrow through the cortex takes place most easily through the canals for the large vessels (canals for the primary and secondary nutrient arteries and the emissary vein) The marrow can often be observed macroscopically as a subperiosteal haematoma around the outer openings of these canals Embolism in the lungs can especially on brushing of the medullary cavity be so extensive that the animal dies during the operation

Operations in the medullary cavity induce characteristic reactions in the periosteum cortex and medullary cavity and these will be discussed separately

Periosteal Reaction

In the periosteum the blood vessels react earlier than the osteogenic cells (Wray, 1963, Trueta 1963) The morphology of the newly formed bone in the present study varied with the vascular reaction Convuluted vessels in one or a few layers, parallel with the cortex and massively filled with Indian

It has been considered that stimulating substances or the loss of inhibitory substances from the underlying cortex whose circulation has deteriorated may initiate periosteal bone formation. Such a stimulating substance named by Lacroix (1951) osteogenin has been considered by several investigators to be capable of stimulating osteogenesis even from immature mesenchymal cells (Levander 1938, Annersten 1940, Goldhaber 1961, Urst 1965, Trueta 1963, Burwell 1964, Puranen 1966).

On statistical analysis of a material studied at an observation time of 1 week in which the medullary cavity of the right tibia was evacuated by suction and of the left tibia by brushing or reaming it was not found however that the extent of the intracortical vascular damage or the amount of bone removed on reaming had any explanatory value for the amount of new bone formed by the overlying periosteum. This was in spite of the fact that the amount of subperiosteally formed bone was on the average greatest on the left tibia where the cortical vascular damage was also the most extensive. Since the medullary cavity was evacuated from both the left and right tibia however the results indicate that other factors than loss of the medullary circulation—which was postulated by Richany *et al* in 1965—were of importance for the periosteal bone formation. One significant factor was probably the bone marrow which was squeezed out subperiosteally.

Cortical Reaction

The cortical necrosis could not be delimited by histological methods. Nuclear pyknosis occurred even in viable bone and even when the number of empty osteocytic lacunae was found to have increased in the central and inner parts of the cortex with increasing observing times, nuclear material was still observed in the inner avascular part of the cortex during an observation period of at least 4 weeks. Neither could any well defined borderline be drawn between nucleated and non nucleated areas in the cortex. The cortical damage caused by the reaming and other operations in the medullary cavity was therefore evaluated on the basis of the Indian ink filling of the intracortical vessels in preparations studied at short observation times.

In that part of the cortex which had retained its circulation after the operation many of the blood vessels increased in calibre during the first week postoperatively and during the second week the bone canals around these vessels widened. Many of the bone canals began to close again however after an observation time of about 4 weeks and in this way the circulation from the periosteum through the outer part of the cortex to its inner part and to the medullary cavity became concentrated to a number

growing animals and reached its maximum about 2 weeks after the operation

All rabbits, both growing and adult, formed more bone subperiosteally in the treated tibia than on the control side. The amount of newly formed bone varied greatly between different animals. In the growing animals bone was formed on the treated tibia mainly during the 2nd week postoperatively and on the control tibia during the 3rd and 4th weeks. In the adult animals a considerably smaller amount of bone was formed than in the growing animals and an almost significant increase in bone formation on both tibias was only obtained when animals observed at 1-4 weeks were compared with those observed at 8 weeks.

The cause of the increased periosteal bone formation could only be partially elucidated in this investigation and appeared to some extent to differ for the formation of lamellar bone and the formation of woven bone.

The formation of lamellar bone which is the most usual type of periosteal bone formation in the rabbit after operations in the medullary cavity, appears to be an acceleration or revival of normal bone formation where the age of the animal and the degree of stimulation determine whether circumferential lamellae or primary osteons are formed. Mature lamellar bone is homogeneous, is not rebuilt and appears also in other respects to be primarily adapted to mechanical demands on the skeleton. It is not clear in what way this bone formation is stimulated but no findings have contradicted the view that it takes place by the mediation of growth and thyroid hormones (Frost 1963) or space polarizing factors (Frost 1963, Schenk 1965). Local stimulating factors cannot be excluded however.

Woven bone especially when it was formed in a large quantity which occurred for example, in trabecular bone was found most commonly in those areas where as a result of the increased intramedullary pressure during the operation considerable amounts of bone marrow were sometimes forced out subperiosteally. The formation of woven bone especially when it occurs in trabecular bone thus seems to be promoted by this subperiosteally forced out bone marrow. Urist & McLean (1952) and Burwell (1967) showed, in transplantation experiments that cells in the bone marrow stimulated by necrosing cortical bone could be induced to form ossicles. These ossicles have a great resemblance to the cavities in trabecular callus tissue which were observed in the present material. Zucman *et al* (1968) found that bone marrow which had become localized subperiosteally was accompanied by considerable local bone formation. Frost claimed (1963) that the formation of woven bone is governed by local factors and not by growth and thyroid hormones and that it has to be reconstructed in order to attain full resistance to mechanical stress.

It has been considered that stimulating substances or the loss of inhibitory substances from the underlying cortex whose circulation has deteriorated may initiate periosteal bone formation. Such a stimulating substance named by Lacroix (1951) osteogenin has been considered by several investigators to be capable of stimulating osteogenesis even from immature mesenchymal cells (Levander 1938, Annersten 1940, Goldhaber 1961, Urist 1965, Trueta 1963, Burwell 1964, Puranen 1966).

On statistical analysis of a material studied at an observation time of 1 week in which the medullary cavity of the right tibia was evacuated by suction and of the left tibia by brushing or reaming it was not found, however, that the extent of the intracortical vascular damage or the amount of bone removed on reaming had any explanatory value for the amount of new bone formed by the overlying periosteum. This was in spite of the fact that the amount of subperiosteally formed bone was on the average greatest on the left tibia where the cortical vascular damage was also the most extensive. Since the medullary cavity was evacuated from both the left and right tibia, however, the results indicate that other factors than loss of the medullary circulation—which was postulated by Richany *et al* in 1965—were of importance for the periosteal bone formation. One significant factor was probably the bone marrow which was squeezed out subperiosteally.

Cortical Reaction

The cortical necrosis could not be delimited by histological methods. Nuclear pyknosis occurred even in viable bone and even when the number of empty osteocytic lacunae was found to have increased in the central and inner parts of the cortex with increasing observing times, nuclear material was still observed in the inner avascular part of the cortex during an observation period of at least 4 weeks. Neither could any well defined borderline be drawn between nucleated and non nucleated areas in the cortex. The cortical damage caused by the reaming and other operations in the medullary cavity was therefore evaluated on the basis of the Indian ink filling of the intracortical vessels in preparations studied at short observation times.

In that part of the cortex which had retained its circulation after the operation many of the blood vessels increased in calibre during the first week postoperatively and during the second week the bone canals around these vessels widened. Many of the bone canals began to close again, however, after an observation time of about 4 weeks and in this way the circulation from the periosteum through the outer part of the cortex to its inner part and to the medullary cavity became concentrated to a number

of larger vessels, which thus took over the function of the destroyed nutrient artery. Those parts of the cortex which had become avascular at the operation were revascularized by 'cutter heads' and broom shaped vascular proliferations. The main revascularization did not appear to take place until after 2 weeks postoperatively. Shortly afterwards bone formation began in resorption cavities often located in parts of the cortex rendered avascular by the operation. After 8 weeks the cortex in growing animals was essentially revascularized while non revascularized areas were still found in the inner part of the cortex in adult animals at the longest observation time of 12 weeks. In cases with very extensive intracortical vascular damage there was a tendency to sequestration of the innermost part of the cortex.

Medullary Cavity Reaction

After brushing or suction the medullary cavity was filled with a clot which contained fragments of disintegrated bone marrow and, after reaming also bone fragments. Occasional blood vessels were sometimes seen to penetrate the cortex from the periosteum, and appeared to be responsible for some local fluid circulation in the medullary cavity. On revascularization of the medullary cavity the blood vessels usually grew out first from those areas of the cortex which had not been directly damaged by the reamer. The first newly formed, immature vessels were observed in the medullary cavity about 1 week postoperatively. The formation of bone trabeculae of woven bone began to take place close to more mature vessels about 30-40 μ in width which could be seen after an observation time of 3 weeks. Resorption of the newly formed bone trabeculae, which began in the peripheral areas of the medullary cavity took place in the close vicinity of blood vessels about 100 μ in calibre which after the resorption of bone trabeculae appeared to become transformed to normal sinusoids. The same type of blood vessel was observed close to trabecular subperiosteally located bone, when callus cavities developed there. A fibrous tissue which was localized as a rule with in the central areas of the medullary cavity and penetrated by narrow blood vessels, often developed in adult animals. The cicatricial tissue did not appear to become completely rebuilt. Foster (1951) observed such medullary fibrosis after a severe circulatory disturbance of the cortex and medullary cavity in adult rabbits while Branemark (1954) found that the bone marrow was completely restored in adult rabbits after scraping out of the contents of the medullary cavity.

Comparison between Reaction in Rabbits and Dogs

A comparative investigation between the reaction on evacuation of the medullary cavity of the femur in adult dogs and the corresponding reaction

in the tibia of adult rabbits showed that the periosteum in the dogs reacted more intensively and that it always formed woven bone which was less common in adult rabbits. After an observation time of 2 weeks there was very active resorption of the newly formed periosteal bone in the dog so that often only small fragments remained at an observation time of 4 weeks. The intracortical vascular damage seemed to have the same origin in the dog as in the rabbit. The reamers which were used in the main experiments viz. hand driven reamers of the Kuntscher model (see Kuntscher 1962) probably gave rise to considerably smaller pressure variations in the medullary cavity however than those used in the rabbit experiments. It is probably for this reason that the intracortical vascular damage seemed to be considerably less extensive in the dogs than in the rabbits after reaming of the medullary cavity. Brushing in the medullary cavity could result in avascularity of two thirds of the cortex however. The reconstruction in the cortex was more active in the dog than in the rabbit. The bone trabeculae in the medullary cavity in the dog appeared to be able to protect some of the endosteal blood vessels during the reaming. Revascularization of the medullary cavity seemed to be initiated more quickly in the dog than in the rabbit but otherwise the courses were similar. Fibrotic tissue which seemed to be at least partly permanent was found in the medullary cavity in all dogs at an observation time of more than 3 weeks.

Complementary Investigations

A logical continuation of this work seemed to be to study how a cortical defect healed with intact and reamed medullary cavities. I made such a study on the rabbit tibia. It was found that when the medullary cavity was intact the defect was bridged over and filled in rapidly by woven endosteal bone. Periosteal callus which also contained cartilage also quickly bridged over the defect and was concentrated to the area outside it. When the medullary cavity had been destroyed the defect was first bridged over by periosteal callus which took place considerably later than when the medullary cavity was intact. Callus was then often found around almost the entire bone but cartilage only outside the defect. During the first 2 weeks of observation the amount of periosteal callus outside the defect was usually greatest when the medullary cavity was intact but at longer observation times it was greatest when the medullary cavity had been destroyed. After destruction of the medullary cavity the defect was revascularized by blood vessels from the periosteum and outer soft tissues but was filled with callus considerably more slowly than when the medullary cavity was intact. A detailed report of the results will be published in a separate paper.

The increase in pressure in the medullary cavity and the subsequent intracortical and subperiosteal marrow emboli was found to be a very important factor for the occurrence of cortical vascular damage and periosteal new bone formation on operations in the medullary cavity. A reduction of the pressure in the medullary cavity during the operation should reduce the marrow emboli and thereby decrease the intracortical vascular damage and the periosteal new bone formation. Such an investigation, in which healing of an osteotomy in the rabbit tibia, fixed stably by compression nailing was studied, has been carried out (Olerud, Danckwardt-Lilliestrom, Lorenz 1969). The pressure in the medullary cavity was reduced during the operation by suction through a drill-hole in the distal tibial metaphysis and the results were compared with a series without such a distal hole. In the series with a peripheral drill hole to reduce the pressure there was less cortical vascular damage and less periosteal new bone formation than in the series in which the pressure was not reduced. Primary bone healing over the fracture gap also occurred in the former cases.

Conclusions

From the series of experiments described in which the medullary cavity of the tibia in growing and adult rabbits and of the femur in adult dogs was destroyed by reaming, brushing or suction the following conclusions could be drawn on the reaction of the diaphysis to these operations

1 The periosteal blood vessels were able to maintain circulation in practically the whole cortical vascular bed when the medullary vessels were destroyed

2 Pressure increase in the medullary cavity which was very easily produced at surgery to this cavity forced bone marrow into the intracortical canals and obliterated these to varying extents. When large pressure increases occurred in the medullary cavity this took place within considerable areas of the cortex

3 The periosteal vessels reacted with increased filling with contrast medium and became tortuous. Blood vessels which were mutually parallel and perpendicular to the surface of the cortex were present when trabecular bone was being formed

4 The periosteum reacted with increased bone formation. In growing rabbits the periosteal bone formation activity increased to a maximum within a few days after the operation and the largest amount of new bone was formed subperiosteally during the second week postoperatively. Adult animals reacted more slowly and showed maximal bone formation activity 2 weeks after the operation. At an observation time of 2 weeks there was pronounced superficial resorption of the newly formed bone in growing rabbits

5 The periosteum formed either mature lamellar bone which was considered to be the result of an acceleration or revival of normal bone formation or woven bone which was believed to result from callus formation promoted at least partly by subperiosteally forced-out bone marrow. The woven bone appeared to be a provisional callus in which reconstruction often began quickly and in which cavities with angiographically normal medullary sinusoids were formed. These cavities seemed to migrate in a central direction with increasing observation times

6 The cortical necrosis could not be outlined by histological methods owing to the fact that nuclear material could remain in necrotic bone during an observation period of at least 4 weeks

The increase in pressure in the medullary cavity and the subsequent intracortical and subperiosteal marrow emboli was found to be a very important factor for the occurrence of cortical vascular damage and periosteal new bone formation on operations in the medullary cavity. A reduction of the pressure in the medullary cavity during the operation should reduce the marrow emboli and thereby decrease the intracortical vascular damage and the periosteal new bone formation. Such an investigation in which healing of an osteotomy in the rabbit tibia, fixed stably by compression nailing was studied, has been carried out (Olerud, Danckwardt-Lilliestrom, Lorenzi 1969). The pressure in the medullary cavity was reduced during the operation by suction through a drill hole in the distal tibial metaphysis and the results were compared with a series without such a distal hole. In the series with a peripheral drill hole to reduce the pressure there was less cortical vascular damage and less periosteal new bone formation than in the series in which the pressure was not reduced. Primary bone healing over the fracture gap also occurred in the former cases.

Statistical Methods

Notation

Number of cases $N=n$

$$\text{Mean } M = \bar{X} = \frac{\sum X_i}{n}$$

where X_i denotes the value for the i th case

Standard deviation

$$s.d. = \sqrt{\frac{\sum (X_i - \bar{X})^2}{n-1}}$$

Standard error of the mean

$$s.e. = \frac{s.d.}{\sqrt{n}}$$

Standard error of the difference between two means \bar{X} and \bar{Y}

$$s.e._{xy} = \sqrt{s.e._x^2 + s.e._y^2}$$

Correlation analysis The correlation coefficient, r of x and y is defined by the expression

$$r = \frac{\sum (x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum (x_i - \bar{x})^2 \sum (y_i - \bar{y})^2}}$$

where \bar{x} and \bar{y} denote the means for the x and y series respectively

Significance tests

1 In testing whether a mean value differs from 0 the following approximately t -distributed ratio has been formed

$$t = \frac{\bar{x}}{s.e._x}$$

2 In testing whether the regression coefficients differed from 0 the method described by Cramer (1945) and Hald (1948) was used

A t value was produced from the expression $\frac{b_1}{s.e._{b_1}}$

7 The extent of the intracortical vascular damage and the amount of bone removed on reaming were not found to have any explanatory value for the amount of newly formed bone in the overlying subperiosteal area

8 Those parts of the cortex which had been rendered avascular by the operation were revascularized from the outer vessel containing parts of the cortex by means of 'cutter heads' and broom shaped vascular proliferations and thereby underwent extensive reconstruction. The areas of the cortex with residual circulation were partly rebuilt the bone canals around many of the blood vessels first becoming wider and then again decreasing in width when the circulation to the inner part of the cortex and to the medullary cavity became concentrated to a smaller number of vessels. The cortex adjacent to the medullary cavity was revascularized also from vessels which had newly formed in the medullary cavity

9 The medullary cavity was revascularized mainly from vessels which in the diaphysis penetrated the cortex from the periosteum. In the medullary cavity trabecular bone was formed close to 30-40 μ wide thin walled vessels and was subsequently quickly resorbed in the close vicinity of vessels approximately 100 μ wide which were later transformed into angiographically normal sinusoids. Small areas of dense fibrous tissue appeared to remain permanently in the medullary cavity

10 On comparison between the reaction of the diaphysis to destruction of the medullary cavity in adult rabbits and adult dogs, it was found that the periosteum reacted more intensively in the dog and always formed woven bone within some area which was relatively unusual in the adult rabbit. The newly formed subperiosteal bone was resorbed very rapidly in the dog. The cortical vascular damage appeared to have the same origin as in the rabbit but the cortical reconstruction was more extensive. In the medullary cavity the same rebuilding process was seen as in the rabbit

Statistical Methods

otation

Number of cases $N=n$

$$\text{Mean } M = \bar{X} = \frac{\sum X}{n}$$

where X_i denotes the value for the i th case

Standard deviation

$$SD = \sqrt{\frac{\sum (X_i - \bar{X})^2}{n-1}}$$

Standard error of the mean

$$SE = \frac{SD}{\sqrt{n}}$$

Standard error of the difference between two means \bar{X} and \bar{Y}

$$SE_{\bar{X} - \bar{Y}} = \sqrt{SE_{\bar{X}}^2 + SE_{\bar{Y}}^2}$$

Correlation analysis The correlation coefficient r of x and y is defined by the expression

$$r = \frac{\sum (x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum (x_i - \bar{x})^2 \sum (y_i - \bar{y})^2}}$$

where \bar{x} and \bar{y} denote the means for the x and y series respectively

Significance tests

1 In testing whether a mean value differs from 0 the following approximately t distributed ratio has been formed

$$t = \frac{\bar{x}}{SE}$$

2 In testing whether the regression coefficients differed from 0 the method described by Cramer (1945) and Hald (1948) was used

A t value was produced from the expression $\frac{b_j}{SE \ b_j}$

3 In testing whether a correlation coefficient differed from 0 the following ratio was produced

$$\frac{r}{\sqrt{1-r^2}} \sqrt{n-2}$$

which—if the true correlation was zero—was considered to be distributed like Student's t , with $n-2$ degrees of freedom

4 In testing differences between means, the following approximately t distributed ratio was formed

$$t = \frac{\bar{x} - \bar{y}}{S.E. \bar{x} - \bar{y}}$$

Significance levels

The term significant is used in accordance with the following convention. If an observed difference between two means is of such magnitude that the probability, P , of obtaining a difference at least as great as the observed value is greater than 0.05 (where the null hypothesis is assumed to hold), then that observed difference is said to be non significant.

If $0.01 < P < 0.05$ the difference is said to be almost significant and is marked*

If $0.001 < P < 0.01$, the difference is said to be significant and is marked**

If $P < 0.001$ the difference is said to be highly significant and is marked***

Multiple regression analysis used in the present study

For a series of n experimental animals we wish to study the relation between a dependent variable y , called the regressand and constituting different ABd areas and a set of explanatory variables $x^{(1)}$, $x^{(2)}$ and $x^{(3)}$. The explanatory variables were similarly localized CDd and DEd areas and also the type of operation.

In order to study the relation between the y and x variables a type of equation must first be laid down. Individual numerical values must also be available for each variable. In the present work equations of the following form have been studied

$$y = b_0 + b_1 x^{(1)} + b_2 x^{(2)} + b_3 x^{(3)}$$

where b_0 , b_1 , b_2 , b_3 are the coefficients which are to be estimated. In estimating these coefficients the principle of least squares has been applied.

The principle of least squares has been described in detail by Cramer (1945) and Hald (1948) who also explain the method of calculating s.e. for the coefficients

Predicted value

The y value for an individual (i) predicted with the aid of the regression equation is defined as

$$b_0 + b_1 x_i^{(1)} + b_2 x_i^{(2)} + b_3 x_i^{(3)}$$

R = Correlation between observed y value and predicted y value

The regression analysis program

In treating the data as stated above the following regression analysis program was used Hodson Thornber Manual for (B34T 8Mar 66) a stepwise regression program Report 6603 Univ of Chicago March 1966 (stencil)

All statistical analyses were performed in collaboration with Associate Professor G Eklund Ph D at the Department of Statistics University of Stockholm

FOREWORD

The background events that ultimately lead to the production of this work take their origin several years ago at Yale Medical Center where the author was a resident in orthopaedic surgery. Interest in biomechanics was expressed at that time to his chief and friend Professor *Wayne Southwick*. As a result of the endeavours and encouragement of Dr. Southwick arrangements were made for a fellowship to pursue this interest. Because of the outstanding work and reputation of Professor *Carl Hirsch* in the field of biomechanics he was approached regarding a position in his Department. Professor Hirsch has contributed generously to this project through his perspective, experience and stimulating discussions. This participation has been very much appreciated.

Acknowledgement is to be given for the valuable assistance of Docent *Ernst Polander* and Doctor *Erlend Lysell* both of whom discussed constructively principles and techniques related to the project. Mr. *Manohar Panjabi* has been a valuable and very essential consultant regarding engineering considerations and applied mathematics. The writer is grateful for the able participation of Mr. *Lennart Beckmann* and Mr. *Bengt Carlsson* in computer programming and Mr. *Bo Erickson* in statistical analysis. Ing. *Hans Hellstrom* has assisted tremendously in innumerable aspects of the project as has Miss *Lena Johnson* and Mrs. *Inga Lisa Elér*. Their help is certainly appreciated. The author wishes also to express his gratitude to Professor *Jan Mellgren*, Docent *Bertil Stenar*, Docent *Leif Lehman*, Docent *Alf Nachemson* and Assistant Professor *Mart Hagü*. Miss *Margareta Apelskog* is to be thanked for secretarial work and Miss *Anita Nordqvist* for photographic assistance.

This investigation was supported by grants from

The Swedish Medical Research Council, Professor Hirsch B70 17X 565 00, The University of Gothenburg, The Carin Trygger Memorial Fund, King Gustaf V Jubilee Fund, The Swedish Labour Insurance Society, Yale University School of Medicine and The National Institute of Health Bethesda, Maryland.

Gothenburg, September 1969

INTRODUCTION

It is as if one undertook for example to investigate a railroad accident solely from a study of the wrecked cars. Much could be learned as to the effect and direction of the destructive forces, the amount of force expended, and the kind of damage done, but more could be learned and future accidents could be better prevented by a study of the normal running time of the trains, their proper relation to each other at the time of the accident, and by an investigation of the signal system and the routine precautions adopted.

This quote from Lovett's classic work on *The mechanisms of the normal spine and its relation to scoliosis* puts into perspective one of the most obvious clinical values of a study of the mechanics of the thoracic spine. It applies with equal relevance to the practical problem of the effects of trauma on the thoracic spine. Pain syndromes related to the thoracic spine, though not as frequent as in the cervical and lumbar spine, do present a significant clinical problem (Hult 1954, Horal 1969). Accurate, reliable information about the normal is generally the basis, if not the prerequisite, for progress in the understanding and treatment of the abnormal.

In the mechanical modelling of the human system one must have access to the relevant biomechanical data before the modelling process can be meaningful. Frequently, however, such data is simply not available or at least not in a form for direct use by the engineer or physical scientist interested in developing a mathematical model. With regard to the spine more attention appears to have been given to the behavior of the cervical and lumbar regions than to the thoracic region although, as mentioned previously, vertebrae in the thoracic region fracture more frequently than other vertebrae.

This above quotation from a dissertation by Orne and Liu in 1969 on *A mathematical model of spinal response to impact* points up quite nicely the more contemporary significance of a study of the mechanics of the thoracic spine.

The goals of this investigation are to provide information about the mechanics of the thoracic spine in man. A review of the literature will show that previous studies on the thoracic spine have defined the relevant problems and provided the background for current investigations. However, there are no studies which employ *precise modern techniques*, use *substantial* numbers of subjects and analyze *all* aspects of the movement of this important part of the vertebral column. It will be noted that there is considerable variance in the writings of previous authors as regards their description of some of the very basic factors involving the patterns and extent of movement in the thoracic spine. There are two precise and accurate methods which have been employed for analysis of motion of the spine. One has been used by Rolander (1966) on the lumbar spine. The other has been employed by Lysell (1969) on the cervical spine. As there are some differences in the information that can be derived from these two techniques, both methods are employed in this investigation. Basic concepts of engineering mechanics play a significant role in the presentation and interpretation of this material. This will most probably be the case for subsequent work. Consequently, an attempt is made to deal with the material in a manner meaningful to mechanical as well as biological interpretation.

There are several important questions the answers to which constitute a thorough descriptive analysis of the motion of the thoracic spine. These questions are:

1. What is the amount and the pattern of flexion and extension? What is the relative amount of each?
2. What is the amount and the pattern of lateral bending and rotation?
3. What are the cephalocaudal variations in the above mentioned patterns and quantities?
4. Is there coupling of axial rotation with lateral bending? What is the direction of the axial rotation?
5. Where are the "Centers of Motion" for the various movements?

6 Are there differences in the motion of the vertebrae when their posterior elements are removed?

The aim of the study is to provide through two separate experimental investigations information that will answer the preceding questions. The first part is a two dimensional analysis in which the motion of one vertebra in relation to the fixed subjacent one is observed under controlled loads. The second part is a truly three dimensional analysis of larger segments of the thoracic spine taken through their various ranges of motion.

ANATOMIC CONSIDERATIONS RELATED TO MECHANICS

To follow is a recapitulation of those aspects of the anatomy that appear to be pertinent to the mechanical behaviour of the spine. A more extensive review of the anatomy is possible by referring to *Fick* (1904) *Strasser* (1913) *Braus* (1921) *Fraiser* (1940) *Hollingshead* (1963) and *Gray* (1967).

Normal Curves and Regional Variations

In the frontal plane the spine appears straight and symmetrical with the exception of a very slight right convex thoracic curve. This is said to be due to the position of the aorta (*Steindler* 1955). Other writers suggest that it is due to increased use of the right hand (*Davis* 1918 *Fraiser* 1940). The relation of handedness has been supported by the observation of left convex curvature in left handed individuals (*Gray* 1936). There are four normal curves in the sagittal plane. The mechanical value of the curves are increased flexibility with stability and augmented shock absorbing capacity. These curves are convex forward in the cervical and lumbar regions and concave forward in the thoracic and sacral regions (Fig. 2). The lumbar curve quite aesthetically is slightly more accentuated in the female. The thoracic curve is primary and can be looked upon as the persisting curve of the embryonic axis (*Fraiser* 1940). The dorsal curve of the thoracic portion of the spine is due to the lesser vertical height of the anterior as opposed to the posterior border of the vertebral bodies (*Gray* 1967). This is also true for the sacral curve (Fig. 2). The thoracic curvature has been observed to increase with age. Below the age of 40 the female thoracic spine is straighter than that of the male. This difference is not found after 40 when the female's dorsal spine becomes as bent as the male's. Such change may contribute to the so called "dowager's hump" (*Loeb* 1967). The convexity of the cervical and lumbar regions is largely contributed to by the relative ventral thickness of the discs. Therefore when distracting forces are applied to the entire spine there is a flattening of the cervical and lumbar lordosis. This is probably due to the deformation of the discs. At the same time the thoracic kyphosis based on osseous asymmetry is almost unaltered (*Kliver* 1963).

Fig. 2 This demonstrates the normal curves of the vertebral column in the sagittal plane. The orientation of the spinous process is also pointed out. (The drawing is reproduced from Gray's Anatomy, 34th Edition, London, 1967, with permission of the publisher.)

From the first cervical to the last lumbar vertebra the bodies increase considerably in mass (Steindler 1935 Gray 1967). In the frontal plane the width of the bodies of the vertebra increases from the second cervical to the third lumbar (Gray 1967). In the thoracic spine the sagittal and frontal diameters are about equal (Gray 1967) or slightly greater in the sagittal plane (Strasser 1913). Measurements by Frazer (1940) of outlines of upper surfaces of thoracic vertebrae revealed consistently greater frontal diameters. In the upper three vertebrae this pattern of a greater frontal than sagittal diameter was more marked than in the lower vertebrae.

Articular Facets and Spinous Processes

Winslow (1732) published probably the earliest definite contribution to the subject of motion in the vertebral column. He included a meticulous description of the apophyseal facets and a discussion of their contact during movements of the spine. Humphry (1859) pointed out that movements permitted in the spine are mainly due to the shape and position of the articulating processes of the diarthrodial joints. It is the orientation of these joints in space that determine their mechanical importance. In the thoracic spine the superior facet is almost flat and directed backwards a little laterally and upwards. The inferior facet is directed forwards slightly downwards and medially (Gray 1967). (See Figs. 2 and 3). This orientation more or less aligns the plane of the joints along the arch of a circle lying in the transverse plane, the center of which is in the vertebral body (Pocknell 1938). Strasser (1913) emphasized the variation of the slopes of the facets in different regions of the spine. Davis (1959) studied nineteen vertebral columns, two of which were freshly macerated from young adult males. Using instruments with line markers at right angles to an edge which could be fitted over the facet, he determined the

Fig. 3 The diagram demonstrates the orientation of the articular facets in the horizontal plane. The intersection point (IP) of Davis' and the geometric arrangement of the annulus fibers are also shown.

intersection points (IP) of lines perpendicular to the plane of the facets (Fig 3) In the upper two thoracic vertebrae this point was found to be well in front of the vertebral body. As observations are made more caudally the point is found to approach and then enter the line of the vertebral bodies. Even lower in the thoracic region the point again leaves but may re enter at the lowest thoracic joint. The freedom of rotation in the thoracic region is thought to be related to this particular orientation of the facets in space (Rockwell, 1938, Steindler, 1955 Lucas and Bressler 1961). One witnesses an abrupt change in the orientation of the plane of the articular joints, when a comparison is made between the thoracic and the lumbar spine. This occurs most commonly at the inferior facet of Th 11 or Th 12 but can be as high as Th 10 (Gray, 1967). Such a vertebra with the plane of the facet joint lying more sagittally than frontally will behave in motion like a lumbar vertebra.

The spinous processes in the upper thoracic region are directed obliquely downwards in the middle they are longer and almost vertical. In the lower thoracic and lumbar regions they are horizontal (Fig 2). In the thoraco lumbar region dorsiflexion is limited by the spinous processes (Åkerblom 1948).

Intervertebral Discs

A number of writers have discussed the significance of the intervertebral disc in relation to the amount of movement between vertebrae (Keller 1924 Beadle, 1931 Miles, 1935 Steindler 1955 Lucas and Bressler, 1961). This organ constitutes 1/3 of the length of the column (Klausen, 1965). Gray (1967) places this estimate at 1/5. The intervertebral disc is comprised of three parts the nucleus pulposus the annulus fibrosus and the cartilagenous end plate. The gelatinous nucleus pulposus contrary to popular opinion is *not a notocord remnant*. It is described as an area of degenerated notocord invaded by fibrocartilagenous cells derived from intervertebral mesenchymal cells (Keyes and Compere 1932 Holtingshead 1965). Microscopically it is composed of a very loose and translucent network of fine fibrous strands. In this there are found a variety of connective tissue cells some spindle shaped others with clear vacuolar nuclei. The latter have been thought to be descendants of the special cells of the embryonic chorda tissue (Beadle 1931). These connective tissue elements lie in a mucoprotein gel which contains various mucopolysaccharides (Hirsch Paulson, Sylien and Snellman 1953 Happey McRae and Naylor 1953 Naylor et al, 1955 Naylor 1962). The nuclear water content ranges from approximately 70-90%. It is highest at birth and tends to decrease with age (Naylor et al 1955). The lumbar nucleus fills 30-50% of the total disc area in cross section (Perey 1957 Nachemson, 1960 Eie 1966). In the low back the nucleus is usually more posterior than central and lies about at the juncture of

the middle and posterior thirds of the sagittal diameter. In general it is placed further forward in the thoracic region (Beadle 1931 Joplin 1935). The size of the nucleus as well as its capacity to swell is larger in the cervical and lumbar region and probably related to the greater flexibility there (Beadle 1931 Gray 1967).

The annulus fibrosus is a portion of the intervertebral disc which gradually differentiates itself from the periphery of the nucleus. This structure is composed of fibrous tissue in concentric laminated bands, approximately six in the thoracic spine (Joplin 1935). The collagen bands run obliquely from one vertebra to the next in a helicoidal arrangement with the fibers in contiguous laminae lying at angles of about 50-70° to each other (Horton 1958 Aylor 1962 Galante 1967) (fig. 3). The annulus fibers are attached to the cartilagenous end plates in the inner zone while in the more peripheral zone they attach like Sharpey's fibers directly into the osseous tissue of the vertebral body (Hirsch and Schajowicz 1952). The third and final portion of the intervertebral disc is that of the cartilagenous end plate. Comparatively little is known about this structure. It is composed of hyaline cartilage and separates the other two components of the disc from the vertebral body (Beadle 1931 Hirsch and Schajowicz 1952).

The above considerations complete the anatomic description of the disc and bring into focus some relevant mechanical properties of the organ. The angular arrangement of the annulus fibers and their strong attachment to the vertebral end plates create mechanical conditions for strong resistance to horizontal translation (Hirsch and Sonnerup 1968). The disc in various manners behaves with visco elastic properties (Virgin 1951). Loads lasting seconds give perfect elasticity curves of the same shape as those observed for hyaline cartilage. If a disc is kept loaded a certain amount of compression occurs until equilibrium is reached (Hirsch and Nachemson 1953). When stress is applied to a normal or slightly degenerated disc the pressure per unit area is about 50% higher in the nucleus. This is probably due to the elastic resistance of the fibers of the annulus. The nucleus can be considered to be subject to Pascal's laws of fluids and consequently is hypothetically incompressible (Arey and Compere 1932 Joplin 1935 Inman and Saunders 1947 Nachemson and Elfstrom 1969). Forces applied to the lumbar nucleus have been explained. They are thought to be transmitted throughout the nuclear material with the forces exerted on the cartilagenous plate and the annulus being equalized. The complete unit of nucleus and annulus is consequently somewhat analogous to a rubber tire with relatively high internal pressure (Nachemson and Elfstrom 1969). Compression of the disc thus results in a bulging of the annulus as observed by Hirsch (1951) and re-evaluated and interpreted by Polander (1966) in the lumbar region of the spine. Horton (1955) maintained that this increase in the

radius of the disc with compression is achieved by the movement of adjacent uniaxial sheets with consequent decrease in Ω (Fig 3) Loss of the elasticity of the disc is described by *Beadle* (1931) as the most conspicuous change differentiating the old or middle aged spine from the young *Naylor et al* , (1955) observed in the aged annulus a loss of gel properties of the nucleus along with increased crystallization of its collagen fibers In the annulus crystallization changes as well as alterations in fibrillar orientation affected its biaxial structure This complex of changes in the disc associated with ageing was interpreted as affecting particularly the function of mobility, which is thought to be decreased in the aged

Ligaments

The major ligaments of the spine from anterior to posterior are as follows the anterior longitudinal ligament the posterior longitudinal ligament the ligamentum flavum (yellow ligament interarcuate ligament) the capsular ligaments the intertransverse ligaments the interspinous ligament and the supraspinous ligament The radiate ligaments anterior costotransverse intertransverse costae tubercle and posterior costotransverse ligaments are listed

Fig 4 Diagrammatic review of ligaments in thoracic spine (From *Lucas and Bressler* 1961)

for the sake of completeness but will not be discussed further (Fig. 4) The anterior longitudinal ligament arises from the tubercle of the occiput and is attached to the atlas and the anterior surface of all vertebrae down to and including a part of the sacrum. It attaches firmly to the edges of the vertebral bodies but is not so firmly interwoven with the annulus fibers of the intervertebral disc (Schmorl and Junghans 1932) The width of the anterior longitudinal ligament is diminished at the level of the disc. It is more narrow and more thick in the thoracic region (Gray 1967) The posterior longitudinal ligament arises from the basilar portion of the occiput and runs over the posterior aspect of all the vertebrae down to the coccyx. It too is interwoven with the intervertebral disc and thicker in the thoracic region. It is however the converse of the anterior longitudinal ligament in that it is wider at the disc and narrower at the vertebral body. Tlaxak (1968) found both the anterior and the posterior longitudinal ligaments to be pre-stressed in the lumbar region.

The ligamenta flava extend from the anterior inferior border of the lamina above to the posterior superior border of the lamina below (Gray 1967). They connect the borders of adjacent lamina from the second cervical vertebra to the first sacral vertebra (Morris 1879). The yellow ligaments are thicker in the thoracic region. They are not paired structures with a midline cleavage as often described but rather like a single structure that extends from the roots of the articular process on one side to the corresponding process on the other (Jamey 1966) (Gray 1967). The ligament is composed of a large amount of elastic fibers (Jamey 1966) and represents the most pure elastic tissue in the human body (Braus 1921). However, Panay (1966) states that with aging there is a type of fibrous substitution which increases the relative amount of fibrous tissue. Skerfving (1958) demonstrated elastic qualities of the yellow ligament from his investigation of the thoracolumbar spine. He noted that the greatest degree of ventroflexion that could be achieved is that in which the interarcuate ligaments are stretched to a maximum. He found that the interarcuate ligaments were the chief factor limiting ventroflexion in the freely dissected lumbar spine. The ligament has been shown to have considerable active compressive force which restricts the intervertebral disc (Nachemson and Evans 1968). These ligaments are also said to protect the disc by slowing flexion. They are thought also to help restore the vertebral column to an erect attitude following flexion. Ford (1966) concluded that though the yellow ligament is probably the only ligament with restrictive activity, such restriction is not a significant factor in the movement of the spine.

The ligaments of the articular capsules are thin and loose. Their attachment is just beyond the margins of the adjacent articular processes. They are shorter and more taut in the thoracic and lumbar region than in the cervical region (Gray 1967). These ligaments do not become taut in ventroflexion before the

affect of the interarcuate ligaments are operative (*Åkerblom* 1948) The intertransverse ligaments pass between the transverse processes In the thoracic region they are characterized as rounded cords intimately connected with the deep muscles of the back The interspinous ligament takes its origin in the ligamentum nuchae and continues along the tips of the spinous processes as a round slender strand down to the sacrum This ligament is not as thick in the thoracic as in the lumbar or cervical region The supraspinous ligament has been observed to be taut on ventroflexion (*Åkerblom*, 1948 *Steindler* 1955) The length of the supraspinous ligament in the lumbar region in maximal ventroflexion is the same as the maximum length obtained with tensile stresses applied directly to the ligament This same phenomenon was noted in testing the interarcuate ligament (*Åkerblom*, 1948)

The ribs and the muscles are not involved in the scope of this investigation and consequently are not included in these anatomical considerations

CONSIDERATIONS TERMS AND DEFINITIONS

The following considerations are applicable to the remainder of this study. Related concepts, terms and definitions involving engineering mechanics are based on the texts of Christie (1952), Timoshenko and Young (1956) and Shames (1966).

The mechanics of the spine can be analysed intersegmentally as the motion of a rigid body (one vertebra) in relation to some reference (the subjacent vertebra). Precise description requires a coordinate system. The system to be employed is a righthand Cartesian coordinate system which is fixed in each vertebra. This reference system applies for the entirety of this work. See Fig. 3.

Motion of a rigid body is a combination of translation and rotation.

Translation—A body is said to be in translation when movement is such that all particles in the body have at a given time the same velocity relevant to some reference.

Rotation—A body is said to be in rotation when movement is such that all particles along some straight line in the body or a hypothetical extension of it have a zero velocity relative to some reference.

Axis of rotation—This is the line of stationary particles whose velocity is zero at the time of rotation.

Coupling—This is applied to motion in which rotation about one axis is constantly associated with rotation about a second axis.

From Fig. 3 it can be seen that the planes can be defined as below.

Sagittal—This is the $x-y$ plane.

Frontal (coronal)—This is the $y-z$ plane.

Horizontal (transverse)—This is the $x-z$ plane.

Flexion—This is movement predominantly in the sagittal plane ventrally directed (i.e. toward the negative direction of the x axis).

Extension—This is movement predominantly in the sagittal plane dorsally directed (i.e. toward the positive direction of the x axis).

Lateral bending (lateral flexion)—This is movement predominantly in the frontal plane to the right (toward the negative direction of the y axis) or to the left (toward the positive direction of the y axis).

Sagittal plane rotation—This is rotation about the z axis (θ). Positive θ is tilting forward as in flexion. Negative θ is tilting backwards as in extension.

Frontal plane rotation—This is rotation about the x axis (θ_x). Positive θ_x

Fig 5 This shows the righthand Cartesian coordinate system to be used throughout this investigation. The system is also indicated with views of a vertebra in the standard planes. (The man and the body planes are reproduced from Gray's Anatomy 34th Edition London 1967 with permission of the publisher.)

is tilting to the left as in left lateral bending, and negative θ_x is tilting to the right in right lateral bending.

Axial rotation—This is rotation about the y axis (θ_y) positive to the left (counterclockwise). Negative θ_y is rotation to the right (clockwise). Clockwise and counterclockwise are as viewed from above. See horizontal view Fig. 5.

Thoracic (dorsal) vertebrae are numbered Th 1–Th 12.

Motion segment—This is constituted by two vertebrae and their adjoining soft tissue (Junghans, 1931). The movement of a given vertebra unless otherwise stated is in relation to the subjacent vertebra.

MOTION IN THE THORACIC SPINE

The following section is a review of the literature. It will be organized in such a way as to point up the basic considerations of importance in describing the motion of the thoracic spine. The inadequacies of previous authors are noted not to detract from their work but to illuminate the problems at hand. The previous studies have laid the more difficult ground work and they provided the foundation on which this and subsequent investigations can be developed. This review does not emphasize historical sequences or development of techniques. The history is thoroughly reviewed by *Elward* (1939) and *Linder* and *Flint* (1940). The technical development is described in the works of *Linder* (1966) and *Lysell* (1969). The major topics in a description of the motion of the thoracic spine can be expressed by the questions heading each section of this review. These questions will constitute the outline for the review of previous investigations as well as the frame work on which the presentation of the material of this study is developed.

What is the Extent and Pattern of Flexion and Extension?

Heber (1827) was probably the first to actually do measurements of the motion of the vertebral spine. From his work based on the analysis of three cadaver spines he concluded that the majority of the *dorsal vertebrae cannot be flexed but only rotated*. *Loxell* (1907) and *Elward* (1939) stated that *flexion is not great and that extension is very slight in the thoracic spine*. *McKendrick* in 1916 studied photos and made measurements of the spine in various attitudes. He observed and emphasized that *there is no flexion in the dorsal spine*. (From *Keller* 1924). *Monro* (1960) based on roentgen studies in flexion and extension stated that *thoracic spine motion under normal conditions and from a practical aspect is almost nonexistent*.

Keller (1924) studied motion of the spine in living subjects by roentgenograms, electrical stimulation of the muscles of the thoracic spine and by careful measurement of markings on the skin. *He disagreed with the statement of immobility of the dorsal spine. The investigations were reported as showing segmental motion in flexion and extension beginning with the 9th dorsal vertebra and moving caudally. He stated that the upper portion has poor motion in the*

Fig 5 This shows the righthand Cartesian coordinate system to be used throughout this investigation. The system is also indicated with views of a vertebra in the standard planes. (The man and the body planes are reproduced from Gray's Anatomy 34th Edition London 1967 with permission of the publisher.)

is tilting to the left as in left lateral bending and negative θ_x is tilting to the right in right lateral bending.

Axial rotation—This is rotation about the y axis (θ_y) positive to the left (counterclockwise). Negative θ_y is rotation to the right (clockwise). Clockwise and counterclockwise are as viewed from above. See horizontal view Fig. 5.

Thoracic (dorsal) vertebrae are numbered Th 1–Th 12.

Motion segment—This is constituted by two vertebrae and their adjoining soft tissue (Junghans 1931). The movement of a given vertebra unless otherwise stated is in relation to the subjacent vertebra.

MOTION IN THE THORACIC SPINE

The following section is a review of the literature. It will be organized in such a way as to point up the basic considerations of importance in describing the motion of the thoracic spine. The inconsistencies of previous authors are noted not to detract from their work but to illuminate the problems at hand. These previous studies have laid the more difficult ground work and they provided the foundation on which this and subsequent investigations can be developed. This review does not emphasize historical sequences or development of techniques. The history is thoroughly reviewed by Elvard (1939) and Anderson and Ekstrom (1940). The technical development is described in the works of Polander (1966) and Lysell (1969). The major topics in a description of the motion of the thoracic spine can be expressed by the questions heading each section of this review. These questions will constitute the outline for the review of previous investigations as well as the frame work on which the presentation of the material of this study is developed.

What is the Extent and Pattern of Flexion and Extension?

Heber (1827) was probably the first to actually do measurements of the motion of the vertebral spine. From his work based on the analysis of three cadaver spines he concluded that the majority of the dorsal vertebra cannot be flexed but only rotated. Lovett (1907) and Elvard (1939) stated that flexion is not great and that extension is very slight in the thoracic spine. McKendrick in 1916, took photos and made measurements of the spine in various attitudes. He observed and emphasized that there is no flexion in the dorsal spine. (From Keller 1924) Monro (1965) based on roentgen studies in flexion and extension stated that thoracic spine motion under normal conditions and from a practical aspect is almost nonexistent.

Keller (1924) studied motion of the spine in living subjects by roentgenograms, electrical stimulation of the muscles of the thoracic spine and by careful measurements of markings on the skin. He disagreed with the statement of immobility of the dorsal spine. The investigations were reported as showing segmental motion in flexion and extension beginning with the 9th dorsal vertebra and moving caudally. He stated that the upper portion has poor motion in the

Fig 5 This shows the righthand Cartesian coordinate system to be used throughout this investigation. The system is also indicated with views of a vertebra in the standard planes. (The man and the body planes are reproduced from Gray's Anatomy 34th Edition London 1967 with permission of the publisher.)

is tilting to the left as in left lateral bending and negative θ_x is tilting to the right in right lateral bending.

Axial rotation—This is rotation about the y axis (θ_y) positive to the left (counterclockwise). Negative θ_y is rotation to the right (clockwise). Clockwise and counterclockwise are as viewed from above. See horizontal view Fig. 5.

Thoracic (dorsal) vertebrae are numbered Th 1–Th 12.

Motion segment—This is constituted by two vertebrae and their adjoining soft tissue (Junghans, 1931). The movement of a given vertebra unless otherwise stated is in relation to the subjacent vertebra.

vertebra as totalling 52.2°. *Lolett* (1905) studied cadavers and a live model whom he both selected and photographed carefully observing that *rotation in the dorsal spine gradually diminishes in a cephalocaudal direction*. He accounted the following degrees of rotation from Th 1-Th 12 51 50 50 49 47 43 40° 34 27 25 21 17. *Steindler* (1955) wrote that rotation was 40° to either side totalling 80° for the dorsal spine. *Lindahl* (1962) reported about 3-4° of axial rotation at each level of the dorsal spine. *Gregersen and Lucas* (1967) inserted *Steinmann* pins in the spinous processes and conducted an *in vivo* investigation with seven subjects. They too found a smaller quantity of motion than did *Lolett* (1905). They stated that there was a total of 74° of rotation in the dorsal spine with an average of about 6° at each level. These writers noted that the amount of rotation in the upper portion of the thoracic spine increases gradually from Th7 upwards. When their subjects were walking however the maximum rotation was observed at the middle portion of the thoracic spine.

Is Rotation Coupled with Lateral Bending?

The issue of the presence or absence of a coupling of axial rotation with lateral bending has received the attention of a number of investigators (*Schull* 1902, *Lolett* 1905, 1907, *Feiss* 1908, *Arkin* 1950, *Steindler* 1955, *Roaf* 1958, *Tidestrom* 1958, *Gregersen and Lucas* 1967). Here too there are differences of opinion. *Roaf* (1958) studied the spines of stillborns and observed that the two motions occurred independently in the thoracic as well as in the lumbar regions. *Lolett* (1905) studied cadaver spines and found rotation and side bending to be inseparable. In the erect and the hyper extended positions he stated that the rotation was coupled with lateral bending. He noted it to be toward the concavity of the lateral curve. In other words when bending to the left the axial rotation of the vertebrae was also to the left. However he reported that in the flexed position the axial rotation was toward the convexity of the curve with lateral bending. To state it differently when the flexed thoracic spine was bent to the left the axial rotation of the vertebrae was to the right. *Arkin* (1950) made roentgen investigations in 5 subjects and reported a tendency for contralateral rotation with lateral bending in both the flexed and the extended positions. *Feiss* (1908) and *Vologodsky* (1911) also reported rotation of the vertebral body to the convexity of the lateral curve. *Tidestrom* (1958) used a mechanical model of the spine to show that based on *Polhem* coupling rotation is a necessary component of side bending in the spine. The direction of the rotation was not stated. *Gregersen and Lucas* (1967) studied living subjects and found the rotation of the vertebral bodies with lateral bending to be toward the convexity of the curve.

Table 1 gives an outline of previous descriptions of thoracic spine motion.

anterior posterior plane *Balle* (1931) also published roentgen studies of vertebral motion. He reported findings which differed widely with those of previous investigations describing segmental motion. *Balle* described an equal amount of flexibility at the various levels.

There is marked variation in reports regarding the total range of flexion and extension in the dorsal spine. *Virchow* (1911) reported intersegmental motion of the thoracic spine. When added they come to 108.0° total flexibility in the sagittal plane between C7 and Th12. *Balle* (1931) found 45.9° extension and 22° flexion. This constitutes a total flexibility of 67.9° with a ratio of approximately 2:1 extension vs. flexion. It is of interest to note that *Fick* (1904) reported total flexibility of the dorsal spine of 135° . *Novogrodsky* (1911) studied four cadaver specimens and reported a total of 62° for the intersegmental motion of the dorsal spine in flexion and extension.

Loebl (1967) conducted in vivo measurements in 176 normal subjects using a special inclinometer and made recordings with the spine in various positions including full flexion and extension. This is not intersegmental motion of course. He reported his findings for total flexion and extension as far greater than is generally described. He noted that the dorsal spine contributed about 25% of the total range of spinal movement in flexion and extension.

What is the Extent and the Pattern of Lateral Bending and Rotation?

According to *Keller* (1924) *Mc Kendrick* reported an absence of lateral flexion in the dorsal spine. *Keller* (1924) wrote that there is poor motion in lateral flexion. He also found the upper portion less mobile than the lower. *Gray* (1967) stated that lateral movement is free in any part of the column. *Lovett* (1905) stated that though the entire dorsal spine participates in lateral bending the larger portion of such motion takes place below the 10th dorsal vertebra. In side bending in all positions he states that the 12th dorsal vertebra behaves as a lumbar vertebra. *Lucas and Bressler* (1961) found the most mobile elements to be between the 3rd and the 7th thoracic vertebra in lateral bending.

Novogrodsky (1911) reported a total lateral flexibility of 76° . *Balle* (1931) found about $2-3^{\circ}$ at each level for a total of 30.6° . *Steindler* (1955) reported $30^{\circ}-40^{\circ}$ on either side or approximately 70° total.

A number of previous investigators agree that there is axial rotation in the thoracic spine (*Weber* 1827, *Hughes* 1892, *Keene* 1906, *Lovett* 1907, *Davis* 1918, *Keller* 1924, *Arkin* 1950, *Steindler* 1955, *Roaf* 1958, *Lindahl* 1962, *Gregersen* and *Lucas* 1967). Their statements disagree however on the amount of rotation, its regional variation and the presence or absence of coupling of this motion with lateral bending.

Hughes (1892) described axial rotation from the 2nd dorsal to the 1st lumbar

vertebra as totalling 52.2° Lovett (1905) studied cadavers and a live model whom he both selected and photographed carefully observing that *rotation in the dorsal spine gradually diminishes in a cephalocaudal direction*. He accounted the following degrees of rotation from Th 1-Th 12 51 50 50 49 47 43 40 34 27 25 21 17 Steindler (1955) wrote that rotation was 40° to either side totalling 80° for the dorsal spine Lindahl (1962) reported about 3-4° of axial rotation at each level of the dorsal spine Gregersen and Lucas (1967) inserted Steinmann pins in the spinous processes and conducted an in vivo investigation with seven subjects. They too found a smaller quantity of motion than did Lovett (1905). They stated that there was a total of 74° of rotation in the dorsal spine with an average of about 6° at each level. The writers noted that the amount of rotation in the upper portion of the thoracic spine increases gradually from Th7 upwards. When their subjects were walking however the maximum rotation was observed at the middle portion of the thoracic spine.

Is Rotation Coupled with Lateral Bending?

The issue of the presence or absence of a coupling of axial rotation with lateral bending has received the attention of a number of investigators (Schulthess 1902 Lovett 1905 1907 Feiss 1908 Arkin 1950 Steindler 1955 Roaf 1958 Tidestrom 1958 Gregersen and Lucas 1967). Here too there are differences of opinion. Roaf (1955) studied the spines of stillborns and observed that the two motions occurred independently in the thoracic as well as in the lumbar regions. Lovett (1905) studied cadaver spines and found rotation and side bending to be inseparable. In the erect and the hyper extended positions he stated that the rotation was coupled with lateral bending. He noted it to be toward the concavity of the lateral curve. In other words when bending to the left the axial rotation of the vertebrae was also to the left. However he reported that in the flexed position the axial rotation was toward the convexity of the curve with lateral bending. To state it differently when the flexed thoracic spine was bent to the left the axial rotation of the vertebrae was to the right. Arkin (1950) made roentgen investigations in 5 subjects and reported a tendency for convex side rotation with lateral bending in both the flexed and the extended positions. Feiss (1908) and Vorogodsky (1911) also reported rotation of the vertebral body to the convexity of the lateral curve. Tidestrom (1958) used a mechanical model of the spine to show that based on Fotherham coupling rotation is a necessary component of side bending in the spine. The direction of the rotation was not stated. Gregersen and Lucas (1967) studied living subjects and found the rotation of the vertebral bodies with lateral bending to be toward the concavity of the curve.

Table 1 gives an outline of previous descriptions of thoracic spine motion.

anterior posterior plane Bakke (1931) also published roentgen studies of vertebral motion. He reported findings which differed widely with those of previous investigations describing segmental motion. Bakke described an *equal amount of flexibility at the various levels*.

There is marked variation in reports regarding the total range of flexion and extension in the dorsal spine. Trenchow (1911) reported intersegmental motion of the thoracic spine. When added they come to 108.0° total flexibility in the sagittal plane between C7 and Th12. Bakke (1931) found 45.9° extension and 22° flexion. This constitutes a total flexibility of 67.9° with a ratio of approximately 2:1 extension vs flexion. It is of interest to note that Fick (1904) reported total flexibility of the dorsal spine of 135° . Novogrodsky (1911) studied four cadaver specimens and reported a total of 62° for the intersegmental motion of the dorsal spine in flexion and extension.

Loeb (1967) conducted in vivo measurements in 176 normal subjects using a special inclinometer and made recordings with the spine in various positions including full flexion and extension. This is not intersegmental motion of course. He reported his findings for total flexion and extension as far greater than is generally described. He noted that the dorsal spine contributed about 25% of the total range of spinal movement in flexion and extension.

What is the Extent and the Pattern of Lateral Bending and Rotation?

According to Keller (1924) McKendrick reported an *absence of lateral flexion* in the dorsal spine. Keller (1924) wrote that there is *poor motion in lateral flexion*. He also found the upper portion less mobile than the lower. Gray (1967) stated that *lateral movement is free in any part of the column*. Lovett (1905) stated that though the entire dorsal spine participates in lateral bending the *larger portion of such motion takes place below the 10th dorsal vertebra*. In side bending in all positions he states that the 12th dorsal vertebra behaves as a lumbar vertebra. Lucas and Bressler (1961) found the *most mobile elements to be between the 3rd and the 7th thoracic vertebra in lateral bending*.

Novogrodsky (1911) reported a total lateral flexibility of 76° . Bakke (1931) found about $2-3^{\circ}$ at each level for a total of 30.6° . Steindler (1955) reported $30^{\circ}-40^{\circ}$ on either side or approximately 70° total.

A number of previous investigators agree that there is *axial rotation* in the thoracic spine (Weber 1827, Hughes 1892, Keene 1906, Lovett 1907, Davis 1918, Keller 1924, Arkin 1930, Steindler 1955, Roaf 1958, Lindahl 1962, Gregersen and Lucas 1967). Their statements disagree however on the amount of rotation, its regional variation and the presence or absence of coupling of this motion with lateral bending.

Hughes (1892) described *axial rotation* from the 2nd dorsal to the 1st lumbar

vertebra as totalling 52° 20'. Lovett (1900) studied cadavers and a live model whom he both selected and photographed carefully observing that rotation in the dorsal spine gradually diminishes in a cephalocaudal direction. He accounted the following degrees of rotation from Th 1 Th 12 51 50 50 49 47 43 40 34 27 25 21 17. Steindler (1905) wrote that rotation was 40° to either side totalling 80° for the dorsal spine. Landahl (1962) reported about 3°-4° of axial rotation at each level of the dorsal spine. Gregersen and Lucas (1967) inserted Steinmann pins in the spinous processes and conducted an in vivo investigation with seven subjects. They too found a smaller quantity of motion than did Lovett (1900). They stated that there was a total of 71° of rotation in the dorsal spine with an average of about 6° at each level. These writers noted that the amount of rotation in the upper portion of the thoracic spine increases gradually from Th7 upwards. When their subjects were walking however the maximum rotation was observed at the middle portion of the thoracic spine.

Is Rotation Coupled with Lateral Bending?

The issue of the presence or absence of a coupling of axial rotation with lateral bending has received the attention of a number of investigators (Schultze 1902, Lovett 1900, 1907, Feiss 1908, Arkin 1900, Steindler 1905, Roaf 1938, Tidstrom 1958, Gregersen and Lucas 1967). Here too there are differences of opinion. Roaf (1938) studied the spines of stillborns and observed that the two motions occurred independently in the thoracic as well as in the lumbar regions. Lovett (1900) studied cadaver spines and found rotation and side bending to be inseparable. In the erect and the hyper extended positions he stated that the rotation was coupled with lateral bending. He noted it to be toward the concavity of the lateral curve. In other words when bending to the left the axial rotation of the vertebrae was also to the left. However he reported that in the flexed position the axial rotation was toward the convexity of the curve with lateral bending. To state it differently when the flexed thoracic spine was bent to the left the axial rotation of the vertebrae was to the right. Arkin (1900) made roentgen investigations in 5 subjects and reported a tendency for convex side rotation with lateral bending in both the flexed and the extended positions. Feiss (1908) and Moragradski (1911) also reported rotation of the vertebral body to the convexity of the lateral curve. Tidstrom (1958) used a mechanical model of the spine to show that based on Polhem coupling rotation is a necessary component of side bending in the spine. The direction of the rotation was not stated. Gregersen and Lucas (1967) studied living subjects and found the rotation of the vertebral bodies with lateral bending to be toward the concavity of the curve.

Table 1 gives an outline of previous descriptions of thoracic spine motion.

Table 1 Outline of Previous Descriptions of Thoracic Spine Mechanics

Author year	No of Subjects investigated	Method	Flexion and Extension	Lateral bending	Rotation	Coupling
Weber I H 1957	3 cadavers 2 males 1 female live males ages 20-40	Direct measurements	The majority of dorsal vertebrae cannot be flexed		Majority of dorsal vertebrae can only be rotated	
	2 cadavers Males 20 Males 40	Attached metal pins to vertebrae studied movement in relation to sub- jacent vertebra			Not thoracic to 1st lumbar 20 yr old 52° 20° 40 yr old 99° 8° Lower portion moved less than upper	
Schultz et al W 1962	Studied mechanical models			Lateral bending without rotation is impossible		Yes
Yick R 1964	1 cadaver	Direct measurement	Total flexibility 13°		Total amplitude 80°	Yes to concavity of lateral curve
Lowett R W 1965	3 subjects cadavers 1 live ages 20-40	Lines in epineurial process and photographic live model	Not an extensive motion for this part of the spine	Greatest in the mid dorsal region	The major motion of the spine is rotation	Yes Rotation to concavity of lateral curve In flexed position how ever rotation as to convexity
	2 cadavers 1 infant 1 adult M	Lines in process and transmission			Can be effectively achieved by pre- surre applied to the appropriate curve pending rels	
Kane C W 1966						

Author	Subject	Method	Population	Lat. and Long.	Result	Concluding
Agall, M 1911	4 Males free females present	Statistical segmental vertical fitted applied electrical analysis	1 to thoracic 1 to lumbar total 170	1 to thoracic 1 to lumbar total 170		Yes to concordance latencies
Agall, H 1911	1 Male	Physical analysis in the range of the position analysis method	Total flexibility latencies to the 1 to lumbar 1080			
Duggan 1918	Statistical no experimental				Free in upper to to of lateral region an gradually lumbar to absent in the lumbar region	
Keller, H 1914	1 male	Rayleigh statistical analysis measuring electrical analysis	Thoracic in the upper regions lumbar lumbar	Per motility in lateral direction direction in the direction	Not more rotation in the upper portion of thoracic thoracic	Yes to the concavity of the lateral curve

Author year	No of Subjects investigated	Method	Flexion and Extension	Lateral bending	Rotation	Coupling
Bakke S N 1931	44 - 0 mal + 24 females ages 3-79	X ray investigation living subjects	There is an even grading of flexibility Total flexibility of thoracic spine 67.9 22 flexion and 45.9 extension	I qual amount of flexibility about 2-3 at each level total 30.6		
Stumiller A 1931	Not stated	In vivo		Noted 30-40 to either side total approximately 70	Described 40 to either side for a total of 80 rotation in thoracic spine	Yes to the convexity of the lateral curve
Roaf R 1938	2 fresh autopsy 1 infant 1 age 8	X ray studies also with pins as markers in spinous processes			Axes of rotation in region of posterior longi- tudinal ligament	No
Takstrom F 1938	Mechanical model	Constructed mechanical model of spine to describe mechanism of coupling		Based on same principal as Polhem coupling rotation as necessary		Yes
Thomson Bresler 1961	3 frozen autopsy specimens ages 2-44	Spine with ligaments loaded and multiple rapid exposure photographs taken		Most flexible ele- ments appear to be between the 3rd and 7th thor- acic vertebrae		

Author	No of Subjects investigated	Method	Illustration	Rating	Conclusion
Day and Trope 1966	13 ages 18-30	In vivo chondrocytology of the epiphyseal plate	Very little thoracic plate motion with no definite pattern		
Gregersen and Juul 1967	7 ages 0-6	In vivo vital staining of the epiphyseal plate			0 at each level rotating from one extreme to the other ~4 total from 1st thoracic to 1st thoracic. The amount increases gradually from the 1st to the 11th thoracic
Loebel W 1967	176 ages 15-84	In vivo rib motion	35 total for thoracic spine (not intersegmental total). The amount was about 1/2 of total flexion and extension for entire spine		

Where are the Centers of Motion for the Various Movements?

The question of a center of motion or an axis of rotation has been discussed by various investigators in relation to movement of all regions of the vertebral column. *Dorogodsky* (1911) considered the center of motion for combined lateral flexion and axial rotation to be somewhere in the anterior portion of the disc. *Dittmar* (1930) demonstrated a moving center of motion in the lumbar spine. *Elward* (1939) stated that there is no single center of motion. *Granturco* (1944) with roentgenologic studies of the lumbar spine observed wide variation of the axis of motion. *Akerblom* (1946) stated that the center of motion was in the center of the disc in the middle of the nucleus pulposus. *Rockwell* (1948) suggested a theoretical center in axial rotation somewhere in the anterior portion of the vertebral body. *Roaf* (1958) suggested that the axis of rotation is somewhere in the region of the posterior longitudinal ligament. *Rolander* (1966) found a large number of motion centers with little or no regional character. *Lysell* (1969) reported in his analysis of cervical spine movement that the axis of rotation for flexion and extension was situated in the subjacent vertebra. It was not possible for him to state whether the axis of motion is fixed or is mobile. He noted that in the combined motion of lateral bending and rotation there was very little movement of a measuring point in the anterior central portion of the moving vertebra. From this observation he deduced that this point was very close to the center of motion.

The broad variations in the description of thoracic spine motion noted in the preceding paragraphs is probably based on several factors. The investigators employed different experimental methods. Few subjects were analyzed in most instances and the techniques of observation were rather imprecise. There is variation of opinion on several points. The extent of motion in flexion and extension and lateral bending does not seem to be at all agreed up. The question of the presence or absence of coupling of lateral bending with axial rotation remains controversial concerning both its existence and direction. The descriptions of the regional variations within the thoracic spine are not consistent as regards each of these movements. The questions of the existence and position of centers of motion and the possibility of their movement remain unsettled. There is a paucity of information on the actual pattern of intersegmental motion.

PART I

TWO DIMENSIONAL ANALYSIS WITH CONTROLLED LOADS

Method

Material

The material for these experiments was removed at the time of routine necropsy at one of the three following institutions: University Hospitals (Gothenburg), Vasa Hospital (Gothenburg) and City Hospital (Malmö). The entire thoracic spine or some major portion of same was removed with a small portion of the attached ribs and the adjoining musculature. Table 2 summarizes the relevant data on the subjects from which the material was removed. There were 10 specimens in this part of the investigation. The age range is 16 to 83 years. Specimens with tumors, fractures from patients with scoliosis and from patients with metabolic diseases known to affect bone were not included.

Handling and Preparation of Test Material

A fresh specimen was received sealed in a plastic bag. A roentgenogram was taken while the material remained sealed. A motion segment for this part of the investigation was always made up of one of the following: Th 1-2, Th 3-4,

Table 2. Autopsy Material Part 1

Subject	Years of Age	Sex	Cause of Death
I	64	F	bronchopneumonia
V	71	F	respiratory and circulatory insufficiency
VI	83	F	arteriosclerosis with cerebral infarction
VII	37	F	rupture of basilar aneurysm
VIII	16	F	status epilepticus with tetanic cerebralitis
IX	33	F	diabetes mellitus with neuropathy
X	49	F	respiratory insufficiency
XI	46	M	myocardial infarction
XII	50	M	pulmonary edema
XIII	64	F	myocardial infarction

Th 5-6, Th 7-8, Th 9-10 or Th 11-12 On the basis of the roentgenograph and direct anatomical evaluation by the author the specimen was cut so as to include as many of the above defined motion segments as the material would allow (Due to damage or errors at the time of removal from the body the entire thoracic spine was not always usable) The remaining portion of the ribs were dissected away The muscles were removed and the ligaments preserved All soft tissue was removed from the superior one third of the more cephalad vertebrae and the inferior one third of the more caudad vertebrae of each motion segment Thus and all handling of the specimen unless otherwise stated was carried out in a specially constructed high humidity chamber This chamber maintained a relative humidity of 95 % or greater The importance of maintaining a high humidity to preserve the physical properties of the annulus and the longitudinal ligaments has been well demonstrated by Hirsch and Galante (1967) Calante (1967) and Tlaczuk (1968) Specimens that were not to be analysed immediately were labeled sealed and preserved in a deep freeze at -25°C There is evidence that freeze storing does not affect the physical properties of bone (Elians 1957 Sedlin and Hirsch 1966) the annulus fibers of the disc (Hirsch and Galante 1967 Galante 1967) nor the ligamenta flava (Åkerblom 1948)

The motion segment(s) (MS) was prepared for testing as described below Those that had been stored by deep freeze were permitted to thaw overnight at $+6^{\circ}\text{C}$ while still sealed The unfrozen MS was treated as follows in the high humidity chamber The MS was balanced in a special metal tray so that the disc was horizontal with a flat level surface This sometimes necessitated removal of a portion of the more caudal spinous process The caudad member of the MS was fixed with a polyester cast (Hirsch 1964) Due to the marked vertical direction of the spinous process in the middle portion of the thoracic spine (Fig. 2) it was sometimes necessary to remove the distal portion of the spinous process of the cephalad vertebra This was done so that the upper vertebra would not be fixed by the polyester A polyester cast was also constructed about the superior one third of the cephalad vertebra (Fig 10 No 5) This cast conformed to the general configuration of the vertebra and its top was horizontal and level (checked with spirit level) When the polyester had hardened the MS with the metal tray was sealed in a plastic bag and nails were affixed to the vertebra Two nails were placed anteriorly at each end of an imaginary vertical line 20 mm long The middle of this line was in the midline of the frontal plane of the vertebra and at approximately the middle of the height of the disc at that point This would be nails AS and AI shown on the sagittal plane of Fig 6 Nails PS and PI shown on the same diagram were placed in the spinous processes in the same sagittal plane as nails AS and AI and also vertical to each other Nails RS and RI were placed on the right side

of the vertebra midway the anterior posterior diameter of the body. The nails both lie in the frontal plane and vertical to each other. Their heights corresponded approximately to those of the anterior nails AS and AI respectively. Positions of nails LS and LI had the same specifications but were placed on the left side of the vertebra. Nails RS, RI, LS and LI are shown in the frontal and horizontal planes of Fig. 6. Due to vertebral asymmetry and measuring error the above defined positions of the nails represent accurate approximations and not precise relationships. All nails were affixed through the plastic seal. The MS at this point was ready for analysis.

Experimental Apparatus

The experimental apparatus used in this part of the present investigation is the same equipment as was employed by Hirsch (1951) then subsequently modified and used by Rolander (1966). The same methods of calibrations and the same errors of measurement apply. The reader is referred to the latter reference for detailed description of the equipment and its use. The salient features of the testing material are summarized below. The equipment is photographed and shown in block diagram (Figs. 7 and 8).

The *compression apparatus* is designed so that a loading force of a known quantity, position and direction can be applied to the MS. The load is powered by compressed air. The amount and rate of application of the load can be controlled by standard valves. The load can be varied from 0-200 k.p. and is recorded through electro-dynamometers. A trolley resting on four ball races resting on a steel plate is placed between the loading edge and the top of the MS. This arrangement permits the specimen to rotate about some axis parallel to the loading edge and to translate along some axis perpendicular to it (Fig. 7 No. 2).

Movement of the specimens in the horizontal ($x-z$) plane was recorded by *displacement gauges* (Fig. 7 No. 4). *Extensometers* (Fig. 7 No. 5) were used to record motion in the vertical planes sagittal ($y-x$) and frontal ($y-z$). In both cases motion is transformed into an electrical impulse created by the displacement of the antiferromagnetic stainless steel tip of a brass shaft inside an electromagnetic coil. This arrangement is called a *differential transformer* (Fig. 7 No. 9). There is an error of measurement inherent in any such motion gauge. In the case of the horizontal gauge when the specimen rotates about its z axis (as an example see sagittal plane Fig. 6) the new position of the measuring point lies on the arch of a circle having a radius equal to the length of the measuring arm (approximately 80 mm). As the vertical displacement is ± 2.5 mm the correction for the horizontal displacement is given by the sine of a very small angle. Consequently it does not affect the recorded value. In

Poentgenograms were taken employing a portable *Schonander* machine with a 2 mm focus. Those used for measuring were taken at a target to focus distance of 1 meter with about 10 cm between the center of the target and the film. Poentgenographs were taken of a notched radiopaque measuring instrument at five positions in the 5 mm focus to film range in which the measuring points (nails) would be found. The distance between the same two points represented on each of the five roentgen films was measured. The mean of these measurements was taken. The actual distance was then measured on the instrument. The measurement on the radiograph was found to represent an 88% enlargement of the actual distance. This information is employed in all calculations based on roentgenographic measurements under the above conditions.

An *Amsler planimeter* was employed to measure the area of a tracing of the horizontally sectioned disc of each motion segment after testing was completed. The accuracy of this instrument in the stated measurement was 0.10 cm.

Procedure for Analysis of Motion Segments

The sealed MS with its nails in place and the lower vertebra fixed in the metal tray was attached firmly to a loading platform in the compression device. The MS was positioned so that its sagittal plane could be roentgenographed. The platform was then rotated 90° and its frontal plane similarly pictured. The horizontal displacement gauges and extensometers were then attached as indicated in Fig. 6 (sagittal plane). The calibrations were checked. By employing a scale on the compression device (reading accuracy ± 0.25 mm) and a pointer it was possible to make an accurate approximation of the diameter of the vertebral body in the sagittal and the frontal planes. From these diameters the 25, 50 and 75% positions shown in Fig. 9 could be determined for the two planes. These positions are employed in order to apply loads to the MS in such a way as to simulate the different movements of the spine. They have the advantage of making comparisons of different motion segments more meaningful in that they have all been loaded at relatively the same points.

The extensometers and horizontal displacement gauges were put into place to prepare the MS for testing. The extensometers were held in position by rubber bands attached to an encircling brass cage. The brass cage is also affixed to the loading platform. By adjusting the tension and position of these rubber bands the extensometer could be balanced with its points positioned in shallow holes drilled in the previously described nails. The horizontal gauges were similarly affixed to their appropriate nail heads with rubber bands. All measuring points were derived from points on the specimen. The extensometer itself recorded all vertical motion in relation to the subjacent vertebrae.

BLOCK DIAGRAM

Fig 8 Diagrammatic representation of equipment (P) is load applied to motion segment

the case of the vertical motion gauge the horizontal displacement of the measuring point is along the arch of a circle with a radius equal to the distance between the tips of the gauges legs. This distance is $25 \text{ mm} \pm 5 \text{ mm}$. Because of the relatively short radius for the vertical gauge there could be a large percentage of error in the vertical displacement if there was a large horizontal displacement. The fact is, however, that the horizontal displacement has been quite small both in relative and absolute terms (Rolander 1966). Horizontal displacement was also very small in this investigation. The median horizontal displacement for any given increment of force is estimated at 0.01 mm for this series.

The information from the extensometers and displacement gauges was fed into a recording system. This system included an amplifier, a channel selector and a recorder (Figs 7 and 8). The reading error on the recorder was $\pm 0.001 \text{ mm}$ and $\pm 0.1 \text{ kp}$.

An electrically driven humidifier with hose and a fiber glass horn at the end was employed. Its purpose was to maintain a high humidity at that point in the procedure when it was necessary to disrupt the plastic seal.

The forces to be applied were between 10-40 kp 20-50 kp and 30-70 kp for the upper middle and lower two motion segments respectively. The ranges were selected so as to effect gradations of movement. The intent was to apply enough of a load to assure significant motion but to avoid deformation of the bone. At the same time the design was to select a range that could reasonably be assumed to include and exceed that of the superincumbent weight of the body. This is discussed in more detail subsequently.

The loading tests were conducted in the following manner. The load was applied at the various positions 50° 25° and 75° first in the sagittal plane then the MS was rotated 90° and the loads were applied in the three positions for the frontal plane. For example Th 12 would be loaded in the sagittal plane at the 50° position with 10 kp followed by serial additions of 10 kp to 20 30 40 and finally up to 50 kp. These increments and ranges of load were not followed precisely but served as guidelines. However the precise load for each recorded movement of the specimen was indicated by the recorder. After loading at the 50° position the subject was then similarly loaded at the 25° and the 75° positions. Each series of loads at a given position was followed by a 5 minute pause for the residual deformation to pass. The resultant position was then recorded. Between the 25° and the 75° positions a very small external force (a light touch with a probe) was sometimes applied to move the specimen toward the initial starting position. This resultant position was recorded and subsequent motion taken in relation to it.

The rotation test was carried out as follows. A threaded steel bar 4 mm in diameter and 17 cm long was pointed at one end. This bar was drilled through the body of the superior (free) vertebra of the MS. The bar was placed horizontal to the loading platform and in the upper one third of the vertebral body at approximately the middle of its anterior-posterior diameter (Fig. 10 No. 1). A metal ring was secured between two ordinary nuts at either end of the bar. The rings were positioned 4.5 cm from the respective entrance and exit of the bar into and out of the vertebra. This positioning caused the lever arm of the moment and thus the force to vary directly with the frontal diameters of the vertebrae. Each ring was wired to a cable which was fashioned to accommodate a series of measured weights at its distal end. A system of pulleys was constructed which could be adjusted to correspond to the height and horizontal position of the attached end of the cable. The cable was held perpendicular to the bar and in the same horizontal plane. The pulley system could be adjusted to maintain these same conditions with the directions of the cables reversed. Small grooves had been cut into the necks of the nails at positions L5, I1, RS and RI (Fig. 6 horizontal plane). Specially constructed plexiglass connectors were employed. They fit into the groove of the nail on one end and accepted the displacement gauge on the other. This arrangement made it

- Ⓐ at the 25% position $d/4$ (flexion)
- Ⓑ at the 50% position $d/2$ (neutral)
- Ⓒ at the 75% position $3d/4$ (extension)
- Ⓓ is the anterior-posterior diameter of the vertebral body

- Ⓐ 25% $d/4$ (lateral bend g)
- Ⓑ 50% $d/2$ (neutral)
- Ⓒ 75% $3d/4$ (lateral bending)
- Ⓓ frontal diameter

Fig 9 Diagram to show determination of loading position in sagittal and frontal planes
See text for explanation

The *paired* horizontal displacement gauges provided information about relative horizontal motion between the vertebrae. There were no external reference points. With these conditions prevailing any extraneous motion of the compression apparatus could not affect the recorded information which represented the movement between the two vertebrae.

The specimen was first pre stressed. This variable was introduced to standardize the starting points and to minimise hysteresis. *Jargin* (1951) stressed human intervertebral discs with the same load one minute apart. He stated that it was conclusively demonstrated that the hysteresis during the second test was always appreciably less than during the first test. In this study the pre stress load was applied at the 50% position of the sagittal plane. Its magnitude was 50 kp for the upper two motion segments (i.e. Th 1-2 and Th 3-4), 60 kp for the middle two and 70 kp for the lower two. The load was applied five times. A 5 minute interval was observed before the testing series began. During preliminary experiments it was noted that most (>98%) of the residual deformation (hysteresis) passes in the first minute. After 5 minutes all or nearly all had passed away. Any remaining very small quantity could persist for several hours. Because of this problem any residual deformation lasting more than five minutes was handled by either of two maneuvers depending on the dictates of the experiment. It was either recorded and subtracted from subsequent deformation or taken away by a slight external force. These manipulations made all reading and consequently all motion comparable as far as the starting points were concerned.

The forces to be applied were between 10-40 kp 20-50 kp and 30-70 kp for the upper middle and lower two motion segments respectively. These ranges were selected so as to effect gradations of movement. The intent was to apply enough of a load to assure significant motion but to avoid deformation of the bone. At the same time the design was to select a range that could reasonably be assumed to include and exceed that of the superincumbent weight of the body. This is discussed in more detail subsequently.

The loading tests were conducted in the following manner. The load was applied at the various positions 50° 20° and 75°, first in the sagittal plane then the VS was rotated 90° and the loads were applied in the three positions for the frontal plane. For example Th12 would be loaded in the sagittal plane at the 50° position with 10 kp followed by serial additions of 10 kp to 20 30 40 and finally up to 60 kp. These increments and ranges of load were not followed precisely but served as guidelines. However the precise load for each recorded movement of the specimen was indicated by the recorder. After loading at the 50° position the subject was then similarly loaded at the 20° and the 75° positions. Each series of loads at a given position was followed by a 3 minute pause for the residual deformation to pass. The resultant position was then recorded. Between the 20° and the 75° positions a very small external force (a light touch with a probe) was sometimes applied to move the specimen toward the initial starting position. This resultant position was recorded and subsequent motion taken in relation to it.

The rotation test was carried out as follows. A threaded steel bar 4 mm in diameter and 17 cm long was pointed at one end. This bar was drilled through the body of the superior (free) vertebra of the VS. The bar was placed horizontal to the loading platform and in the upper one third of the vertebral body at approximately the middle of its anterior posterior diameter (Fig. 10 No. 1). A metal ring was secured between two ordinary nuts at either end of the bar. The rings were positioned 4.5 cm from the respective entrance and exit of the bar into and out of the vertebra. This positioning caused the lever arm of the moment and thus the force to vary directly with the frontal diameters of the vertebrae. Each ring was wired to a cable which was fashioned to accommodate a series of measured weights at its distal end. A system of pulleys was constructed which could be adjusted to correspond to the height and horizontal position of the attached end of the cable. The cable was held perpendicular to the bar and in the same horizontal plane. The pulley system could be adjusted to maintain these same conditions with the directions of the cables reversed. Small grooves had been cut into the necks of the nails at positions L5 L1 P5 and R1 (Fig. 6 horizontal plane). Specially constructed plexiglass connectors were employed. They fit into the groove of the nail on one end and accepted the displacement gauge on the other. This arrangement made it

- Ⓐ at the 25% position $d/4$ (flexion)
- Ⓑ at the 50% position $d/2$ (neutral)
- Ⓒ at the 75% position $3d/4$ (extension)

- Ⓐ 25% $d/4$ (lateral bending)
- Ⓑ 50% $d/2$ (neutral)
- Ⓒ 75% $3d/4$ (lateral bending)
- Ⓓ frontal diameter

Fig 9 Diagram to show determination of loading position in sagittal and frontal planes
See text for explanation

The *paired* horizontal displacement gauges provided information about relative horizontal motion between the vertebrae. There were no external reference points. With these conditions prevailing any extraneous motion of the compression apparatus could not affect the recorded information which represented the movement between the two vertebrae.

The specimen was first pre stressed. This variable was introduced to standardize the starting points and to minimize hysteresis. Virgin (1951) stressed human intervertebral discs with the same load one minute apart. He stated that it was conclusively demonstrated that the hysteresis during the second test was always appreciably less than during the first test. In this study the pre stress load was applied at the 50% position of the sagittal plane. Its magnitude was 50 kP for the upper two motion segments (i.e. Th 1-2 and Th 3-4), 60 kP for the middle two and 70 kP for the lower two. The load was applied five times. A 5 minute interval was observed before the testing series began. During preliminary experiments it was noted that most (>98%) of the residual deformation (hysteresis) passes in the first minute. After 5 minutes all or nearly all had passed away. Any remaining very small quantity could persist for several hours. Because of this problem any residual deformation lasting more than five minutes was handled by either of two maneuvers depending on the dictates of the experiment. It was either recorded and subtracted from subsequent deformation or taken away by a slight external force. These manipulations made all reading and consequently all motion comparable as far as the starting points were concerned.

The forces to be applied were between 10-40 kp 20-50 kp and 30-70 kp for the upper middle and lower two motion segments respectively. These ranges were selected so as to effect gradations of movement. The intent was to apply enough of a load to assure significant motion but to avoid deformation of the bone. At the same time the design was to select a range that could reasonably be assumed to include and exceed that of the superincumbent weight of the body. This is discussed in more detail subsequently.

The loading tests were conducted in the following manner. The load was applied at the various positions 50° 20° and 75°, first in the sagittal plane then the MS was rotated 90° and the loads were applied in the three positions for the frontal plane. For example Th12 would be loaded in the sagittal plane at the 50° position with 10 kp followed by serial additions of 10 kp to 20° 30° 40° and finally up to 50 kp. The increments and ranges of load were not followed precisely but served as guidelines. However the precise load for each recorded movement of the specimen was indicated by the recorder. After loading at the 50° position the subject was then similarly loaded at the 20° and the 75° positions. Each series of loads at a given position was followed by a 5 minute pause for the residual deformation to pass. The resultant position was then recorded. Between the 20° and the 75° positions a very small external force (a light touch with a probe) was sometimes applied to move the specimen toward the initial starting position. This resultant position was recorded and subsequent motion taken in relation to it.

The rotation test was carried out as follows. A threaded steel bar 4 mm in diameter and 17 cm long was pointed at one end. This bar was drilled through the body of the superior (free) vertebra of the MS. The bar was placed horizontal to the loading platform and in the upper one third of the vertebral body at approximately the middle of its anterior-posterior diameter (Fig. 10 No. 1). A metal ring was secured between two ordinary nuts at either end of the bar. The rings were positioned 4.5 cm from the respective entrance and exit of the bar into and out of the vertebra. This positioning caused the lever arm of the moment and thus the force to vary directly with the frontal diameters of the vertebrae. Each ring was wired to a cable which was fashioned to accommodate a series of measured weights at its distal end. A system of pulleys was constructed which could be adjusted to correspond to the height and horizontal position of the attached end of the cable. The cable was held perpendicular to the bar and in the same horizontal plane. The pulley system could be adjusted to maintain these same conditions with the directions of the cables reversed. Small grooves had been cut into the necks of the nails at positions L5, L1, R5 and R1 (Fig. 6 horizontal plane). Specially constructed plexiglass connectors were employed. They fit into the groove of the nail on one end and accepted the displacement gauge on the other. This arrangement made it

Fig 10 Photograph shows motion segment set up for testing *rotation* (1) metal pin in vertebral body (2) wires through which moment is applied (3) horizontal displacement gauges (4) horn from humidifier (5) polyester cast See text for explanation

possible to record motion in the horizontal (xz) plane (Fig 10 No 3) The axial rotation was then tested by adding measured weights of equal quantity to each cable after the pulleys had been adjusted as described above The initial load to each cable was 0.25 kp The load was then increased on each cable by 0.5 kp increments up to 1.75 or 2.25 kp The cables were arranged to test the MS first in the counterclockwise direction ($+\theta_y$) then in the clockwise direction ($-\theta_y$)

An outline is provided to show the procedure as described above

I Schedule of Testing

A MS was pre stressed at the 50° position in the sagittal plane

B Motion in the sagittal plane was tested

50° position

25° position—flexion ($+\theta$)

75° position—extension ($-\theta$)

C Motion in the frontal plane was tested

50° position

25° position—bending to right ($-\theta x$)

75° position—bending to left ($+\theta x$)

D Motion in the horizontal plane was tested

Counterclockwise vertebral body turns to left ($+\theta y$)

Clockwise vertebral body turns to right ($-\theta y$)

II Loads employed

A Loads for Sagittal and Frontal Testing

Pre stress		Range for Testing
Th 1-2 & Th 3-4	50 kp	10-50 kp
Th 5-6 & Th 7-8	60 kp	20-60 kp
Th 9-10 & Th 11-12	70 kp	30-70 kp

B Loads for Axial Rotation

270-300 kp cm

Range varied directly with frontal diameter of superior vertebra

In Fig. 10 one can see two nails positioned at the side of the upper vertebrae. The nails were placed along a vertical line perpendicular to the loading platform. They were used to check with an additional extensometer (not shown in photograph) for deformation of the vertebra. Several motion segments from different thoracic levels were arbitrarily selected and tested during the pre stress. There was no indication of deformation. In some instances loads up to 100 kp were applied without deformation. During the routine testing of motion loads of such great magnitude were not employed. Most probably for the range of stresses applied in this investigation the vertebrae behaved as rigid bodies.

Removal of Posterior Elements

An additional experimental variable was introduced into the described routine. The variable was introduced in order to compare in the same specimen under the same conditions the motion with and without the posterior elements. It was felt that such comparisons would give some insight into the question of the role, if any, that these elements play in the mechanics of the thoracic spine. For the purpose of this investigation the posterior elements (PE) shall be defined. This term will be used to designate the following structures between any two vertebrae: the facet joints, the intertransverse ligaments, the yellow ligament, the inferior $\frac{1}{2}$ of the laminae and the spinous process. This leaves only the intervertebral disc and the anterior and posterior longitudinal ligaments connecting the two vertebrae.

After the previously described manipulations were completed with the MS remaining in the apparatus the PE were removed. The plastic seal was cut and with ordinary surgical instruments the task was accomplished without having to remove or even change the position of the MS. Fig. 10 shows a MS with this operation completed. When the plastic seal is broken the humidifier (Fig. 10 No. 4) is directed on to the specimen in order to maintain a high humidity. The MS is then loaded again exactly as when it was intact. Thus the MS is tested in the same planes with the same range of loads at identical points of application.

Data Processing Description and Comments

Five discretely increasing loads were applied to each MS at three positions in the frontal and sagittal planes first on the intact vertebra then with the PE removed. There were eight to ten observations of rotation about the y axis resulting from discretely increasing moments on each MS with and without the PE. As there were 50 motion segments, this constituted close to 4 000 angles to be calculated from the raw data. Computer analysis of the data was therefore employed using the following mathematical approach. The rotation of a body in a plane can be determined by the movement of two points of the body in that plane. The movement of the points in each of the three planes is represented by a_1 and b_1 in Figs. 11 and 6. Fig. 6 also explains how these values come from the measuring instruments. The distance B_2 shown in Fig. 11 is measured from a roentgenograph of the MS. The 8.8% magnification is corrected for during the computer analysis of the data. The angle of rotation θ in a given

Fig. 11 Diagram shows information needed to calculate angle of rotation and instantaneous axis of rotation of a rigid body rotating in one plane. A point plotted on the coordinates C_1 and C_2 gives the location of the instantaneous axis of rotation for the body.

roentgenographic plane can be calculated by the formular

$$\theta = [(b_2 - a_1)/B]$$

Information about horizontal movement is provided by a . With the ϵ in formations it is possible to calculate the position of the instantaneous axis of rotation that is the position on coordinates C_1 and C_2

$$C_1 = a_2/\theta$$

$$C_2 = a_1/\theta$$

Cumulative force was plotted against cumulative displacement in angles for all MS in all planes of motion as shown in Figs 12 and 13. From the example given it can be readily observed that the points fit quite nicely to a straight line. This visual observation is supported by statistical evaluation which employed the Method of least squares to test the extent to which the points fit a straight line. Consequently it was possible to extract from the slopes meaningful approximations of the cumulative load and cumulative displacement in angles between the actual experimentally determined points. A load of 6 kp/cm^2 and a moment of 20 $kp\ cm$ were selected as the standard forces to be employed for extensive evaluation. For this load and moment the cumulative displacement in angles of all the MS in all conditions of testing was extracted. This additional analysis of the data was included to offer a meaningful comparison of the motion of a large number of MS from different subjects under conditions of a standardized force and constant relative point of application. These extracted quantities of angle shall subsequently be referred to as the standardized motion(s) (SM).

There are several sources of error operative in the results obtained in this part of the analysis. The errors can be divided into two groups namely those having to do with experimental factors and those related to the mathematical analysis. The mathematical errors arise from the assumption that for the calculation of θ for small angles the movement of the points a_1 and b_1 represent movement along the arch of a circle. This error was calculated for angles of the quantities listed in Table 3. One is reminded that angles presented in the results are cumulative values. The actual calculated angles that go to make up the cumulative values are usually less than 3°. Errors involved in the experimental method are difficult to generalize about as their influence varies tremendously in quantity and direction. It is possible to be specific about such

Table 3 Percentage of Errors in Calculated Angles

Calculated angle	1	3	5	8	10	1
Percentage of error	0.02%	0.14%	0.39%	0.99%	1.46%	3.58%

After the previously described manipulations were completed with the MS remaining in the apparatus the PE were removed. The plastic seal was cut and with ordinary surgical instruments the task was accomplished without having to remove or even change the position of the MS. Fig. 10 shows a MS with this operation completed. When the plastic seal is broken the humidifier (Fig. 10 No. 4) is directed on to the specimen in order to maintain a high humidity. The MS is then loaded again exactly as when it was intact. Thus the MS is tested in the same planes with the same range of loads at identical points of application.

Data Processing Description and Comments

Results and Interpretation

The Effects of Various Loads and Moments on the Movement of the Motion Segments

The data for all fifty MS was plotted as shown in Figs 12 and 13. This particular example is used because it is thoroughly representative. In this section the motion referred to is rotation in all instances. There was generally little or no motion when the MS was loaded at the 50% position. This was the case for both the frontal and the horizontal plane. In the sagittal plane there was generally more motion when the load was applied to simulate flexion of the movable vertebra (25% position) than when the load was applied to cause extension (75% position). In the experiments on axial rotation (θ_y) there was a pattern for the slopes of the force deflection curves. They tended to increase as observations of the different MS were made in a cephalocaudal sequence. See Fig 14. Table I in the Appendix gives the basis for statistical interpretation of differences in these slopes for all subjects. The standardized motion of the various levels for the different subjects is given in Appendix Table II. The means of the total motion in various experimental conditions are shown in Appendix Table III. It is apparent that when flexion is simulated the movement is almost always greater than when extension is simulated. If these two movements are combined the means of the combined sagittal motion can be seen to increase at the more caudal levels. See Fig 15. Statistical evaluation of this trend gently supports this statement and its graphic representation at the 0.10 level of confidence. Appendix Table IV gives the information for this statistical interpretation. Similar evaluation of the SM in the frontal plane graphically and statistically implies more frontal motion at the lower MS when compared with the intermediate levels. See Fig 16 and Appendix Table IV. A comparison of the means of the SM in axial rotation at the different levels shows this motion to decrease as the observation moves caudally. Here again statistical analysis lends corroborative support with a 10% level of emphasis (Fig 17. Appendix Tables III and IV).

Based on this data certain statements can be made about the behavior of the lumbar spine MS when known forces are applied under controlled conditions. Graphical and statistical analyses of the material show greater motion in flexion

errors only in a specific set of circumstances. Some of the errors have been discussed. Other errors are those having to do with the measurements of B_z (± 0.5 mm) and the variations in the positions of the nails and extensometers. To provide some guideline to the experimental errors a geometrical analysis and a mathematical estimate of the errors of a representative case were carried out. The conditions were chosen so as to facilitate the effective operation of the errors. This analysis estimates the maximum error of θ to be in the range of 3-4 %.

HORIZONTAL PLANE

See text for explanation

than extension. There is a definite tendency for greater flexion and extension at the lower levels as compared with the intermediate levels. Motion in the frontal plane (lateral bending) shows also a tendency for larger quantities of movement at the lower MS when compared with the intermediate levels. Axial rotation is greater in the upper levels and shows stepwise decrease as observations are made cephalocaudally.

Effects of the Removal of the Posterior Elements

The behavior of the MS with the posterior elements removed is also recorded on Figs 12 and 13 and Appendix Tables II and III. In the two dimensional

Fig. 15 Graphical representation of means of standard axial motion of combined flexion and extension at the different vertebral levels with and without the posterior elements
See text for description

was employed on the hypothesis that the mean difference with and without the PE is zero (Brownlee 1966). This test was carried out for all the types of motion described except that at the 50° position in the frontal and sagittal planes. Statistically significant differences were noted in the slopes after removal of the IF at the 75° position in the sagittal plane and with the tests for axial rotation. These differences were significant at the 0.05 level of confidence and in the positive direction for the cumulative angle values. In other words graphic and statistical analysis of the data shows that with removal of the IF there is a greater motion per unit force when such force is applied to simulate extension and axial rotation.

The standardized motion (SM) was also studied to recognize any effects of the elimination of the IE. Here too the differences were evaluated by the

Fig 14 Comparison of slopes for cumulative moment and cumulative motion in angles for different vertebral levels in one subject. See text for discussion.

studies it can be said that removal of the PE effected significantly the motion in several parameters. Visual evaluation of the slopes as seen in Fig 12 reveals slopes of a more acute angle with the horizontal at the 25° and 75° positions in the sagittal plane after removal of the PE. Furthermore, the slopes were shifted toward a higher range of cumulative angle values. This general trend could be observed as an over all trend by inspection of the other 40 graphs like Fig 12. The same generalization characterizes the change in axial rotation demonstrated in Fig 13. Statistical analysis was carried out. The Sign test

processing took into account radiologic magnification and adjusted the C_1 & C_2 calculations to make the location of the IAP correspond accurately to the image on the film.

Fig. 18 shows representative examples of the IAR in the sagittal plane. The majority of the MS showed clustering of the points within a 5 mm diameter circle. In all instances the axes for extension were located above those for flexion. Those for extension were located above the disc and more anteriorly while those for flexion were found below the disc and posterior to the extension axes. In a small minority of examples the axes for extension were above the body of the moving vertebrae. This can be seen in subject VIII Th 5-6 Fig. 18. When the posterior elements were removed the IAR generally remained clustered and moved only a small distance away from the corresponding points for the intact vertebrae (subject IX Th 9-10 Fig. 18). The representa-

LATERAL BENDING

Fig 16 Graphic representation of means of standardized motion of combined lateral bending at the different vertebral levels with and without the posterior element See text for description

Sign test In these observations differences were noted at the 25° and 75° positions in the sagittal plane and with axial rotation. These differences again are in the direction of an increase of motion and they are significant at the 0.05 level of confidence. Figs 15, 16 and 17 show graphically all the differences in the amount of motion in the various planes with and without the posterior elements.

Instantaneous Axes of Rotation

Calculations of the instantaneous axes of rotation (IAR) were carried out and plotted on tracings of the corresponding radiographic views of all the motion segments of the three youngest and one of the older subjects. Data

tive examples of IAP for the frontal plane are depicted in Fig 19. Here as in the sagittal plane there was clustering of the points. On left lateral bending (positive rotation about the x axis) the IAR tended to cluster to the right of the midline. Conversely with right lateral bending (negative rotation about the x axis) the IAR were observed to be to the left of the midline. This pattern was evident in the data presented by Rolander (1968) with movement of the lumbar spine in the frontal plane. Again ablation of the posterior elements resulted in only minimal movement of the still clustered IAR (Fig 19 subject VIII Th 9-10).

The IAP in the horizontal plane during axial rotation has been calculated and depicted in the same manner in Fig 20. All motion segments for subjects VII and VIII were analysed. It should be mentioned that for technical reasons these points are not considered to be entirely as accurate as for the preceding two planes. Rotation was tested in two segments counterclockwise then clockwise and generally the points were clustered. The groups of IAR tended to be in the midline at different points along the x axis. Removal of the posterior elements resulted in a somewhat greater shift here than was noted in the preceding two planes (Fig 20 subject VII Th 11-12). These observations seem to fit with the movement of Davis (1959) intersection point and the suggestions by other writers that the orientation of the plane of the facet joints influence the axis of axial rotation (Pockwell 1938, Gregerson & Lucas 1967). The IAR were not found as far anteriorly in the vertebral body as where Lysell (1969) suggested the possible center of axial rotation in the cervical spine might be located.

Age and Motion

The experimental control of applying loads at relatively the same positions (0-25 and 75% of the diameter in the plane in which motion was tested) allowed a comparison between different subjects. The total SM in the sagittal and frontal planes was combined for the Th 7-8 MS of each subject and plotted against age in years. Similarly total rotation at the same MS (Th 7-8) for each subject was plotted. Inspection of Figs 21 and 22 shows that there is no evidence in this data of any relationship between amount of motion and age of subject. This was the case for axial rotation as well as for the total motion in the sagittal and frontal planes.

Motion ratio and Total Motion

It has been suggested that the amount of allowable motion at a given intervertebral segment may be related to the amount of disc material and the diameter of the vertebral body in the plane in which the predominant motion

Fig. 21 Graph shows total motion (combined sagittal and frontal planes) for Th 7-8 of each subject as related to age of subject. See text for discussion.

takes place (Fick 1904 Keller 1924 Wiles 1935 Lucas and Bressler 1961). In evaluating this hypothesis it was possible to make further use of the experimental controls employed and look at the SM as related to the disc heights and diameters. For all the motion segments the disc height was measured on roentgenogram at three points: the anterior, middle, and posterior regions of its diameter in their sagittal views and the right, middle, and left regions in their frontal views. An average of each set of three values was taken as the disc height. The disc diameter was then measured on roentgenograph in the two

AGE AND MOTION

Fig Graph shows the amount of axial rotation of Th 7-8 of each subject as related to age of subject See text for discussion

planes The disc height/disc diameter ratio was calculated for each MS in the frontal and sagittal roentgenographic planes This ratio of disc height/disc diameter is what is meant by motion ratio

In order to test the hypothesis that an increase in motion ratio is correlated with an increase of motion the Th 7-8 MS for all subjects was selected A ranking of the motion ratio for Th 7-8 of each subject revealed almost no tendency for correlation This was the case for motion in both the frontal and the sagittal planes with or without ablation of the posterior elements See Table V in Appendix

Comments

Certain considerations are relevant regarding the interpretation of the findings in this part of the investigation. In an analytical study of a mechanical nature it is important to have information about force and deformation. When such information is analysed it is possible to recognize any constant relationship between the two variables and make predictions about one based on a knowledge of the other and the constant. In engineering terms this straight line relationship between force and deformation (rotation in angles) is characterized by a *spring constant*. This is represented by the slope of the line plotted in Fig. 23 and for all the data as shown in the exemplary Figs. 12 and 13.

Fig. 23 See text for explanation

It has been shown previously that for the range of forces involved in this experiment the cumulative forces and angles of rotation strongly tend to form a straight line relationship. Thus it can be stated that in this series for the forces employed the MS behaved in a manner that can be analysed in mechanical terms of a spring constant.

The range of the loads employed in this study in relation to some gross estimates of the loads imposed by gravity at the various thoracic vertebral levels has been considered. These are given in Table 4. The calculations are

based on the estimated percentages of body weight above different vertebral levels (Ruff 1960 Hen et al 1968) applied here to the perennial hypo

Table 4 Estimation of Superincumbent Body Weight of a Hypothetical Subject and Experimental Load Ranges at Various Levels

Vertebral Level	% of Superincumbent Body Weight	Weight in 70 kg Subject	Hypothetical Load Kp/cm ²	Range of Experimental Loads Kp/cm ²
Th1	9%	6.3 kg	1.4	~ 10.8
Th9	33%	23 kg	4.7	2.4-7.3
Th12	47%	33 kg	6.3	~ 1-5.0

thetical 70 kg man. In order to estimate the area of the vertebrae at the different levels the average area for the corresponding level found in this investigation was employed. The experimental load range was arrived at by dividing the Kp load range used in this experiment for the different levels by the average area of the vertebrae for that level. The lower portion of the experimental range is close to or within the range of the estimated load imposed by the approximated superincumbent body weight. Estimations of the loads involved during the characteristic movements of the living thoracic spine would be extremely difficult. Nevertheless it appears that the selected force of 6 Kp/cm^2 is probably a good deal greater than the gravitational forces. A relatively high moment 20 $Kp\cdot cm$ was chosen to observe rotation. In both instances a relatively strong force was employed in order to bring out the cephalocaudal differences and the intact compared with the ablated PE differences. The knowledge and control of the forces made possible meaningful and reliable interpretations of the observed differences.

Several generalizations regarding cephalocaudal variations seem reasonable based on this series. The lower portions of the thoracic spine behaved more like the lumbar spine than did the middle portion. This was apparent in two characteristics: (1) greater motion in the sagittal plane; (2) less motion in the horizontal plane (axial rotation). The vertebrae in the central portion tended to behave as a homogeneous group. In lateral bending tests no salient pattern of variation at the different levels emerged.

Removal of the posterior elements resulted in greater motion in flexion in extension and in axial rotation. This information has direct clinical applicability as regards traumatic and surgical involvement of these structures. Two dimensional analysis of the motion of these segments in the frontal and sagittal planes of their roentgenographic projections provide clinically useful

information. While the surgeon is of course thinking always in three dimensions the actual pictures before him are usually those of frontal and sagittal roentgenograms. Therefore, if he keeps in mind that the two dimensional analysis is a simplification of the true motion the information described here can be effectively utilized in clinical evaluations.

PART II

THREE DIMENSIONAL ANALYSIS

Method

Material

The sources of the specimens are the same as for those employed in part I of this study. Table 5 summarizes the relevant data on the specimens used in this part of the investigation. There were 17 subjects. Their ages ranged from 5 to 83 years. Specimens with tumors, fractures from patients with scoliosis and from patients with metabolic diseases known to affect bone were also excluded from this group.

Table 5 Autopsy Material Part II

Subject	Years of Age	Sex	Case of Death
1	84	M	pulmonary edema
	41	F	hemorrhage of external iliac artery
3	44	F	uremia
4	8	M	cerebral vascular insufficiency
5	49	M	dialytic nephrosclerosis
6	4	F	osteosarcoma carcinoma
7	57	F	bronch pneumonia
8		F	chronic pulmonary disease with electrolyte imbalance
9	35	M	hypernephroma pneumonia
10	36	M	bilateral pulmonary emboli
11	16	F	respiratory insufficiency by asphyxiation (suicide)
12	57	M	cerebral vascular insufficiency
13	79	F	fracture of rat on of liver
14	19	M	congenital heart disease
15	16	M	asphyxiation by drowning
16	8	M	post-traumatic intracranial hemorrhage
17	5	M	cerebral contusions

Handling and Preparation of Test Material

As in Part I of this investigation the specimens were protected from physical changes by storing in a deep freeze. When working with the specimen it was always sealed in a plastic bag or kept in the high humidity chamber. A roentgenogram of the specimen was taken in its sagittal and frontal planes. Based on the roentgenograph and anatomical evaluation it was cut so as to preserve either the upper or lower 6 or 8 vertebrae for testing. The roentgen apparatus could not accommodate any larger segment of the adult thoracic spine. It was possible to test much larger portions of the small 5 year old spines. The thawed specimen was handled in the following manner. The ribs were dissected away. The majority of the para spinous muscle mass was removed leaving a small amount of muscle tissue as an additional protective seal against dehydration of the deeper structures. Four 0.8 mm steel balls were inserted into each vertebra. The anterior ball (A) was inserted in the midline of the anterior portion of the vertebral body a few millimeters below the upper end plate and just beneath the cortex. The posterior one (P) was similarly inserted at the base of the spinous process as close as possible to the midline sagittal plane. The remaining two balls R and L were also inserted subcortically but at the right and left side of the vertebral body and slightly posterior to the middle of its anterior posterior diameter. The preparation was then fixed in a brass cup by at least one vertebra held with polyester of the type described in Part I of this work. The brass cup was specially constructed to fit into the roentgen apparatus. The specimen and cup were placed in a plastic bag. A hook was attached to the uppermost vertebra by screwing it into the cancellous bone of the body. The specimen was then ready for examination.

Apparatus and Experimental Technique

As stated previously the technique and apparatus for this portion of the investigation is the same as that used by *Lysell* (1969). A more detailed description is available in that thesis. To follow is enough detail to provide the reader with a basic understanding of the technique without having to actually search the above work.

See Fig. 24. This equipment is constructed so that the object Table (A) is circular and can rotate about a vertical axis which runs through a reference point (R). (R) is a steel ball 8 mm in diameter placed in a pillar of plexiglass. The object table can be locked in several positions. For this study +22.5 (pos I) and -22.5 (pos II) were employed. A roentgen film holder (B) lies behind the reference point and perpendicular to the rotation plane of the object table. The film holder can be displaced parallel to the 1' square ruler (C). The front of the film holder is perforated and can be attached to a

Fig. 4. Roentgen apparatus. For description see text.

vacuum. This makes it possible to secure an uncovered roentgen film fixed flat against the holder. The position where the brass cup which holds the specimen is located is represented by F. Between the roentgen tube and the object table there is a metal rod (D) which has a hole in its flattened top. The position of this hole is such that an imaginary line drawn through its center and the center of the reference point is parallel with the rotation plane of the object table. The described line is also perpendicular to the axis of rotation and to the film plane in position 0 (the middle position between positions I and II). Before measuring the tube is adjusted and fixed so that the reference point is projected in the center of the projected hole (of the metal rod) onto the roentgen film. With this adjustment it follows that a roentgen beam from the focus through the reference point strikes the film perpendicularly if it is in position 0.

Handling and Preparation of Test Material

As in Part I of this investigation the specimens were protected from physical changes by storing in a deep freeze. When working with the specimen it was always sealed in a plastic bag or kept in the high humidity chamber. A roentgenogram of the specimen was taken in its sagittal and frontal planes. Based on the roentgenograph and anatomical evaluation it was cut so as to preserve either the upper or lower 6 or 8 vertebrae for testing. The roentgen apparatus could not accommodate any larger segment of the adult thoracic spine. It was possible to test much larger portions of the small 5 year old spines. A hook was attached to the uppermost vertebra by screwing it into the cancellous bone of the body. The specimen was then ready for examination.

Apparatus and Experimental Technique

As stated previously the technique and apparatus for this portion of the investigation is the same as that used by *Lysell* (1969). A more detailed description is available in that thesis. To follow is enough detail to provide the reader with a basic understanding of the technique without having to actually search the above work.

See Fig. 24. This equipment is constructed so that the object Table (A) is circular and can rotate about a vertical axis which runs through a reference point (R). (R) is a steel ball .8 mm in diameter placed in a pillar of plexiglass. The object table can be locked in several positions. For this study $+22.5^\circ$ (pos. I) and -22.5° (pos. II) were employed. A roentgen film holder (B) lies behind the reference point and perpendicular to the rotation plane of the object table. The film holder can be displaced parallel to the I square ruler (C). The front of the film holder is perforated and can be attached to a

During the actual taking of the roentgenographs of the specimens the object table is first turned to position I (Fig 2a A) The film holder is moved to the left and the left part of the film is covered with a roentgen opaque shield The exposure for this position can be made The object table is now rotated 45° to position II (Fig 2a B) The film holder is displaced to the right and the right part of the film is covered Now the second exposure can be made Considerable care is taken not to alter in the least either the position of the specimen or the position of the film on the holder during the time between the two exposures

The geometry the mathematical analysis employed and the method of measuring on the radiographs are exactly as described on pages 23-29 in the thesis by *Lysell* (1969) Only the coordinate system is different in this investigation

Manipulation of Specimen

The specimen was moved in flexion and extension and lateral bending by attaching thin metal wires to the previously described hook in the uppermost vertebra See Fig 2b Nine exposures were taken of motion in the sagittal plane starting with full extension and ending with full flexion Three of these exposures were to the extension side of the resting position (Pe) (position of spine with no external load applied) An exposure of the Pe was made along with more to the flexion side of the Re Motion in the frontal plane totalled seven exposures three on either side of the Re and the Ie itself This movement was started with full right lateral bending and ended with full left lateral bending Axial rotation was taken from complete counter clockwise rotation to complete clockwise rotation in seven steps with three on either side of the Pe and including the Pe This maneuver was made possible by drilling a stainless steel pin through the body of the uppermost vertebra Through a specially constructed metal fork which could be attached to this pin the rotary force could be applied

The end points for the full range of these motions was readily recognizable by this investigator At the extremes of the ranges there is a gradually increasing moderate resistance followed by a distinct abrupt rapidly increasing strong resistance This latter very narrow range of resistance was taken as the end point for the total ranges in these experiments

Data Processing Description and Comments

The data from this portion of the study was analysed by two approaches From the primary measuring points on the radiograms it was possible to obtain precise information about the position in space of each of the 4 steel balls placed in each vertebra Mathematical computation included calculation of

Results and Interpretation

The Pattern of Motion

The 5th thoracic vertebrae of subject 3 was selected to demonstrate the pattern of motion for it is thoroughly representative both qualitatively and quantitatively. Its pattern of motion is depicted in Figs 27, 28 and 29. One will note immediately that there is very little motion. This is perhaps a salient characteristic of the movement of the thoracic spine.

Sagittal motion is depicted in Fig. 27. Looking at the $x-y$ plane, the relative motion can be defined as translation in the negative direction of the x axis and rotation in the positive direction about the y axis. The dashed line connects the A and P points in the position of full extension. In the neutral or resting position they are connected by the uninterrupted line. The position of full flexion is indicated by the point-dashed line. The range of extension can be seen to represent about 1/3 of the total range. The movement of points R and L in Fig. 27 is over-simplified due to the limitation of space in which to represent it.

The view of this motion is shown again on the same figure in the $x-z$ plane. The subjacent reference vertebra 6 is not shown on this view. In this plane the predominant motion one notes is translation along the x axis.

The pattern of motion in lateral bending is shown in Fig. 28. A study of the e diagrams shows that in motion from full right lateral bending to full left lateral bending there is translation along the y axis in the positive direction and rotation about the x axis in the positive direction. There is also a rotation about the y axis in the positive direction. This is seen best in the horizontal ($x-z$) view. However, it can also be observed by a study of the motion of points A and L in the frontal ($y-z$) view. In different terms it can be stated that in this example with lateral bending the vertebra rotates into the concavity of the lateral curve. There is coupling of rotation about the x and y axes with directions positive about both axes. *Lye* (1969) found such motions to be strongly coupled and in the same directions in the cervical spine.

Axial rotation is patterned in Fig. 29. The specimen is taken from a full counterclockwise to a full clockwise position. The coupling of rotation about the

Fig 26 Diagrammatic representation of steps within ranges of motion studied See text for explanation

numerical vectoral quantities of the relative positions of the secondary measuring points A P R and L in adjacent vertebrae. Secondary measuring points are mathematically determined points which facilitate the study of relative motion by establishing symmetrical and comparable neutral positions (Lysell 1969). Thus it was possible to plot the positions of these points in relation to the subjacent vertebra at various steps within the total range of movement in the sagittal frontal and horizontal planes. Points were plotted from all the subjects in the three planes of motion. It is from this analysis that it was possible to determine the actual patterns of motion.

The second portion of the data analysis begins with the positions of A P and L on the x , y and z coordinates in relation to the reference point (R). Calculations are made of a number of different informations to be reported and discussed in the following section of this investigation. Even though the experimental error is small it proved to be out of the range of precision necessary for standard available mathematical approaches. Consequently a special system had to be devised one that would allow for the experimental error and still provide a true three dimensional analysis of the motion. Mathematical evaluation of the amount of the resultant error has found it to be 4° for angles of 5° and 8° for angles of 10°.

The mathematics were worked out in cooperation with a mechanical engineer. The details and the theoretical basis of this analysis is to be published in a separate work (Panjabi and White 1969).

From the 17 subjects included in this part of the study the motion of 141 vertebrae was analysed by two programs producing 219 000 informations.

Results and Interpretation

The Pattern of Motion

The 5th thoracic vertebrae of subject 3 was selected to demonstrate the pattern of motion for it is thoroughly representative both qualitatively and quantitatively. Its pattern of motion is depicted in Figs 27, 28 and 29. One will note immediately that there is very little motion. This is perhaps a salient characteristic of the movement of the thoracic spine.

Sagittal motion is depicted in Fig 27. Looking at the $x-y$ plane, the relative motion can be defined as translation in the negative direction of the x axis and rotation in the positive direction about the z axis. The dashed line connects the A and P points in the position of full extension. In the neutral or resting position they are connected by the uninterrupted line. The position of full flexion is indicated by the point dashed line. The range of extension can be seen to represent about 1/3 of the total range. The movement of points R and L in Fig 27 is over simplified due to the limitation of space in which to represent it.

The view of this motion is shown again on the same figure in the $x-z$ plane. The subjacent reference vertebra 6 is not shown on this view. In this plane the predominant motion one notes is translation along the x axis.

The pattern of motion in lateral bending is shown in Fig 28. A study of these diagrams shows that in motion from full right lateral bending to full left lateral bending there is translation along the z axis in the positive direction and rotation about the x axis in the positive direction. There is also a rotation about the y axis in the positive direction. This is seen best in the horizontal ($x-y$) view. However, it can also be observed by a study of the motion of points A and P in the frontal ($y-z$) view. In different terms it can be stated that in this example with lateral bending the vertebra rotates into the concavity of the lateral curve. There is coupling of rotation about the x and y axes with directions positive about both axes. *Lysell* (1969) found such motions to be strongly coupled and in these same directions in the cervical spine.

Axial rotation is patterned in Fig 29. The specimen is taken from a full counterclockwise to a full clockwise position. The coupling of rotation about the

x and y axes can again be observed in both the frontal and horizontal views. This is the same coupling as was seen in lateral bending except that the directions are reversed due to the fact that the specimen was moved from counterclockwise to clockwise the negative direction about the y axis rather than in the positive direction.

Flexion and Extension

From the three dimensional analysis information regarding linear movement in the sagittal plane was extracted. This was done in order to show for large segments of the thoracic spine what portion of the total sagittal motion could be called extension. Thus the linear motion of ball A of the top vertebrae of the thoracic spine segment was divided into two portions. These portions were that to the extension side of the initial resting position (positive direction of x axis) and that to the flexion side of the initial resting position (negative direction of x axis). The segments of the upper one half of the spine showed a mean percentage extension of 33.4% of the total range. The middle and lower portion showed means of 26.3 and 33.3% respectively. The mean of the percentages of extension for all segments tested was 31.0%. The figures on which these statements are based are given in the Appendix Table VI.

The movement to the flexion side and to the extension side of the resting position was compared. For each vertebra the movement was separated into what was called the first and second portion of θ range. The first portion was the movement between full extension and the resting position. The second portion was the movement between the resting position and full flexion. Only those vertebrae about which there was information on all the steps along the total range were used. Inspection of Table VII in the Appendix shows that for a great majority of the vertebrae the amount of extension was less than the amount of flexion. For each of the vertebrae Th 1-11 inclusive the means of the movement in the first and then the second portion of range θ were taken. In order to look at the over all pattern for the spine the mean total extension for all the vertebrae in all the subjects was compared with the same total for flexion. The extension was less than the flexion (14 vs 19) and was 42% of the full sagittal motion. The full motion in the sagittal plane was evaluated for this series by taking the total θ for each vertebra in the different subject. The mean for each level was then calculated and is recorded in Table 6. The angles for individual subjects and vertebrae are given in Table VIII of the Appendix. Fig. 30 shows the average motion for the different levels of the spine. The total of the averages for flexion and extension is 34.4. The pattern of cephalocrudal variation shows a tendency for greater sagittal motion at the lower levels.

Lateral Bending

The motion here is evaluated as described in the preceding paragraph for flexion and extension except that it is rotation about the x axis (θx) that is under consideration. The total average movement for all the eleven vertebrae is 22.0° . These observations suggest no particular pattern for cephalocaudal variation. See Table 7 and Fig. 31. In the Appendix Table IV gives the data for specific subjects and vertebrae.

Axial Rotation

Similar analysis of this movement resulted in the mean angles shown in Table 8. The total of the means for axial rotation is 41.1° . Fig 32 suggests less axial rotation at the lower vertebral levels. Appendix Table X gives the θ_y for the various individual subjects and vertebrae. The attachment of the rotation apparatus to Th 1 precluded complete observations at that level.

Coupling

This aspect of thoracic spine mechanics was evaluated by analysis of the data in the following manner. The coupling to be examined is the motion about the x and y axes when the spine moves in lateral bending. In other words, what is the association, if any, of θ_y and θ_x during lateral bending? In this section the motion discussed is in relation to the external reference point (R) (Fig 24) not to the subjacent vertebra. Examination of the data revealed some associated rotation about the z axis during lateral bending. Thus, it was

AXIAL ROTATION

Fig 3 Graph shows cephalocaudal variation of axial rotation for the subjects in this series. See text for explanation.

necessary to look at the variation of θ and θ_y when θ_x was the predominant motion. In the lateral movement under analysis that is from complete right lateral bending to complete left lateral bending the major motion is about the x axis to the positive direction. When there is coupling about the x and y axes a graphic plotting of the cumulative θ_x and θ_y of the vertebrae under analysis should show any association that exists. In a direct variation coupling the cumulative curve would be positive on both the θ_y and θ_x axes. An inverse relationship coupling but in the opposite direction would show negative on the θ_y axis. Finally with little or no association (no coupling) the line of cumulative θ_x and θ_y values would hunt about the zero point of the θ_y coordinate. As there was some associated θ rotation it was necessary to look simultaneously at the cumulative θ_x and θ_z angles. This would make possible a differentiation between specific θ_x and θ_y coupling and generalized associated movement including some element of change of θ_y and θ with θ_x . In this particular coordinate system and for this particular motion a positive θ_y associated with positive θ_x is the same as rotation of the vertebral body into the concavity of the lateral curve. The 2nd, 6th and 11th thoracic vertebrae were selected for analysis of the question of coupling. Though it may seem unlikely on initial inspection a study of Figs 33, 34 and 35 will elucidate certain information about coupling. At the Th2 level four subjects were available for analysis. For all subjects analysed there was a definite direct relation between

LATERAL BENDING

Fig 31 Graph shows cephalocaudal variation of lateral bending for the subjects in this series. See text for explanation.

Axial Rotation

Similar analysis of this movement resulted in the mean angles shown in Table 8. The total of the means for axial rotation is 41.1° . Fig 32 suggests less axial rotation at the lower vertebral levels. Appendix Table A gives the θ_y for the various individual subjects and vertebrae. The attachment of the rotation apparatus to Th 1 precluded complete observations at that level.

Table 8 Means of Total Axial Rotation for the Various Subjects at Each Level

Vertebral Level	1	2	3	4	5	6	7	8	9	10	11

Coupling

This aspect of thoracic spine mechanics was evaluated by analysis of the data in the following manner. The coupling to be examined is the motion about the x and y axes when the spine moves in lateral bending. In other words, what is the association, if any, of θ_y and θ_x during lateral bending? In this section the motion discussed is in relation to the external reference point (R) (Fig 24) not to the subjacent vertebra. Examination of the data revealed some associated rotation about the z axis during lateral bending. Thus, it was

AXIAL ROTATION

Fig 3 Graph shows cephalocaudal variation of axial rotation for the subjects in this series. See text for explanation.

necessary to look at the variation of θ_x and θ_y when θ_x was the predominant motion. In the lateral movement under analysis that is from complete right lateral bending to complete left lateral bending the major motion is about the x axis to the positive direction. When there is coupling about the x and y axes a graphic plotting of the cumulative θ_x and θ_y of the vertebrae under analysis should show any association that exists. In a direct variation coupling the cumulative curve would be positive on both the θ_y and θ_x axes. An inverse relationship coupling but in the opposite direction would show negative on the θ_y axis. Finally with little or no association (no coupling) the line of cumulative θ_x and θ_y values would hunt about the zero point of the θ_y coordinate. As there was some associated θ rotation it was necessary to look simultaneously at the cumulative θ and θ_x angles. This would make possible a differentiation between specific θ_x and θ_y coupling and generalized associated movement including some element of change of θ_y and θ with θ_x . In this particular coordinate system and for this particular motion a positive θ_y associated with positive θ_x is the same as rotation of the vertebral body into the concavity of the lateral curve. The 2nd, 6th and 11th thoracic vertebrae were selected for analysis of the question of coupling. Though it may seem unlikely on initial inspection a study of Figs 33, 34 and 35 will elucidate certain information about coupling. At the Th2 level four subjects were available for analysis. For all subjects analysed there was a definite direct relation between

θy and θx At the same time there was very little associated cumulative movement about the θ_z axis This series shows at the Th2 level a definite pattern of coupling of axial rotation into the convexity of the curve with lateral bending (Fig 33)

The motion of Th6 was analysed and depicted in the same manner as Th2 See Fig 34 One can recognize here that there is again a direct variation of θx and θy The relation is not as strong nor as distinctly different from the relation of θx and θ_z as was noted for the Th2 vertebrae There were 11 subjects in which Th6 could be studied The 8 subjects depicted in Fig 34 all showed a relation of positive θy associated with a positive θx In each of the 8 individual cases the positive association of θx and θy was stronger than that of θx and θ_z for the particular subject under analysis In the remaining 3 cases this situation did not exist Some of the examples at the Th6 level which did not show the pattern of coupling at Th2 actually showed the reverse They showed rotation of the vertebrae into the convexity of the lateral curve Thus at the Th6 level for this series coupling of axial rotation with lateral bending was found in 8 of 11 examples The rotation in these examples was into the convexity of the lateral curve and not as marked as at the Th2 level

With the same graphing techniques the motion of five Th11 vertebrae was studied Fig 35 shows that some of the subjects demonstrated coupling of motion with positive θx and θy varying directly In these examples 3 out of 5 of the subjects show the coupling of the pattern described above Here too the trend is less strong than at the Th2 level

Average Curvature

So as to have some mathematical description of the steepness of the arch that one vertebra takes in relation to the subjacent one the average curvature was taken Curvature is defined as one divided by the radius ($1/r$) Thus a very flat arch (that of a huge circle) will have a small value for curvature A steep arch will have a relatively larger value The point used for curvature was the relative motion of point (ball) A between adjacent vertebrae This quantity was calculated for each step in the sagittal and the frontal planes and the average taken for each plane The data is shown for sagittal and frontal motion in Appendix Tables XI and XII respectively The ratio $1/r$ is multiplied by 100 for convenience Examination of the means of the average curvature for each level in different subjects provides some impression of the overall pattern There is no suggestion of any scheme of cephalocaudal variation in the sagittal plane in the steepness of course traveled by the different vertebrae relative to their subjacent member (Fig 36) In frontal plane motion there is a suggestion of a more steep pattern in the vertebrae at the lower thoracic levels (Fig 37)

Instantaneous Helical Axis of Motion

The instantaneous motion pattern for a rigid body can be analysed as a simple screw motion. The screw motion is a superposition of rotation and translation about and along the same axis (Christie 1952 Shames 1966). This axis has the same direction as the resultant of the three rotation components about the x, y, z axes. Vector quantities θ^* for rotation and a δ^* for translation lie on this axis. The above described axis is referred to as the *helical axis of motion*. For a given moving rigid body the location of this axis and the

from position 2 to 3 in Fig. 26. This motion is in the $-\theta y$ direction. The major rotation is negative about the y axis with a very small component of rotation about the z and x axes. The translation and rotation of the helical axis is also indicated in this example.

designation of the quantity of its rotation and translation constitute a complete precise three dimensional analysis of the motion. In this section a description of the use of this three dimensional analysis on the intersegmental motion of the thoracic vertebrae of man will be presented and exemplified.

The reference in relation to which the motion is analysed is point A of the subjacent vertebra. The coordinate system is thus established about point A and the respective planes indicated as shown in Fig 38. The position of the resultant axis for any given rotation can be defined by the point at which the axis intersects any two of the three planes M_{xy} , M_{xz} and M_{yz} . Data analysis included calculation of this point of intersection of the helical axis with each of these three planes. This calculation was done for every step of flexion extension lateral bending and rotation for all the subjects and all the vertebrae. Data processing also included calculation of the ratio of translation to rotation (RTR) along the helical axis.

Three examples have been selected quite deliberately to elucidate the characteristic positions of the helical axis of a vertebra in each of the three predominant patterns of motion in the spine. The first example Figs 39 and 40 gives the helical axis of motion of Th10 (subject 19) moving in the sagittal plane on the flexion side of the resting position. This would be movement from position 5 to 4 on Fig 26. The position of the helical axis in relation to the x , y and z axes locates the line about which all points in the vertebra are rotating. Also the relative quantities of rotation about the three axes are indicated by the extent to which the helical axis parallels the respective x , y and z axes. Examination of Fig 39 shows the position of the axis graphically and Fig 40 shows its approximate position in relation to the two vertebrae. Additional information in the graphic demonstration is the direction of the helical axis indicated by the arrow which shows that the major rotation is positive about the z axis. The lack of parallelism about the y or x axis indicates that there is only a small element of rotation about them. The rotation is given by the mathematical analysis and is the vector sum θ^* of the instantaneous rotation about the x , y and z axes. The translation of the axis is expressed by the vector sum δ^* of the instantaneous translation along the x , y and z axes. These quantities are indicated in Fig 39. Their symbols are given in Fig 38.

Motion in the frontal plane is illustrated by subject 6 Th7 moving from position Re to 3 (Fig 26). The position and direction of the axis indicates predominant rotation about the x axis in the positive direction (Fig 41). There is also a moderate amount of y axis and some z axis rotation involved. In this example the helical axis actually goes through the vertebra (Fig 42). The θ^* and δ^* are also shown to complete the analysis by describing the respective rotation and translation of the axis. The motion in the horizontal plane is similarly indicated in Figs 43 and 44. The subject is moving in the clockwise direction.

Flexion Extension

are precision and thoroughness of description. Expression of motion with the helical axis also allows for direct comparison of the motion of bodies of different sizes and shapes. Consequently there are no limitations on the choice of the measuring points and secondary measuring points are not required. It would not have been possible to introduce the helical axis of motion without the previously mentioned three dimensional mathematical analysis.

Comments

The important characteristics of this part of the investigation are the fact that larger segments of the spine were tested and a truly three dimensional analysis of the motion was achieved. The method of testing the vertebrae with in the full range of their allowable motion afforded observations that may be considered representative of their in vivo behavior. The patterns of motion of the individual vertebrae seem to have their own variation of the spinal theme of translation and rotation. In the thoracic spine both elements are small. Information about the controversial question of coupling of motion in the thoracic spine is provided by this three dimensional analysis of the data. The graphic representation of the sample vertebrae (Th2) showed rotation of the vertebral body into the *concavity* of the lateral curve. The graphic analysis of the cumulative angles of rotation showed the same coupling but less markedly and less frequently in the middle and lower portions than in the upper. This series supports the conclusion that coupling of the type described is the predominant pattern. However, this pattern diminishes cephalocaudally. It has been shown that there can be essentially no coupling at all or the *reverse* situation of axial rotation into the *convexity* of the lateral curve. This was noted at the Th6 level. This crucial mechanical point about the behavior of the normal thoracic spine based on three dimensional analysis provides important basic background knowledge relevant to the study of scoliosis. In these observations there is again a tendency for the upper part of the thoracic spine to behave somewhat like the cervical spine and the lower part somewhat like the lumbar spine. The pattern of coupling noted to be more marked in the upper thoracic spine is characteristic of the coupling of the cervical spine (Lysell 1969). The data from this section of the investigation displayed a propensity for greater flexion/extension at the lower portion of the thoracic spine. There was also less rotation noted at the caudal end. Greater sagittal mobility and less axial rotation are both characteristics of the lumbar spine (Steindler 1955, Gray 1967, Gregersen and Lucas 1967).

This part of the investigation is thought to contain the initial introduction of a complete three dimensional analysis of intersegmental spinal motion in terms of the *helical axis of motion*. The meaning and interpretation of this type of analysis is described and exemplified. The advantages of such a designation

diameter) to the amount of motion did not show any significant correlation. Examination of the data for cephalocaudal trends regarding the steepness of arch that each vertebra traveled in relation to its subjacent fellow was made. There was no cephalocaudal pattern in sagittal plane motion but a more steep pattern was noted in the caudad half in frontal plane motion.

The rather important and controversial question of coupling was evaluated carefully and the following description is offered. In the upper portion of the thoracic spine there is relatively marked and consistent coupling of axial rotation with lateral bending. The direction of the coupling is such that the *axial rotation of the vertebral body is into the concavity of the lateral curve*. In the middle and also in the lower regions of the thoracic spine this same pattern still exists and probably dominates. However it is neither as marked nor as consistently present. Furthermore the direction of the *coupled axial rotation in the middle regions was noted in some cases to be the reverse of the above described pattern*. A number of observations were made under controlled conditions on the mechanics of the motion segments with and without their posterior elements. The removal of these structures resulted in significant increases in the amount of motion in flexion, in extension and in axial rotation. This information is valuable to the clinician in terms of his understanding of the effects of surgical or traumatic involvement of these structures on the mechanics of the thoracic spine.

Analysis of the data to designate the positions of the instantaneous axes of rotation in the frontal, sagittal and horizontal reontgenographic planes was carried out. These points were clustered and fairly consistently located for the ranges tested. For extension they were above the disc, for flexion they were below. In lateral bending they were at or near the disc and slightly away from the midline to the contralateral side of the direction of lateral bending. The axes in the horizontal plane with axial rotation tended to cluster at points along a line from the anterior middle portion of the vertebra to the region of the spinal canal. Removal of the posterior elements caused a small but definite shift in the location of these clusters.

The portion of this study in which known loads were employed revealed that for the range of loads involved a spring constant could be determined for the relation ship of force and deformation of the motion segments.

From the three dimensional part of this investigation it was possible to introduce the application of the instantaneous helical axis of motion in a bio-mechanical study of the intersegmental motion of the spine. The designation of the motion in this manner is complete, precise, graphic and truly three dimensional. The instantaneous helical axis of motion was shown for three thoracic vertebrae. Each of the three exemplified a different one of the three characteristic movements that is flexion, extension, lateral bending and axial rotation.

SUMMARY AND CONCLUSIONS

The clinical importance of the thoracic spine as regards scoliosis pain syndromes surgical and traumatic considerations provided the motivation for this investigation. It seemed apparent that reliable descriptive information about the normal mechanical function of this region of the spine would serve as a basis for better understanding of disease and therapy. Inquiry of the available literature on the motion of the thoracic spine pointed up the fundamental questions to be answered in a thorough description. Previous studies have not combined precise modern techniques with substantial numbers of subjects and reported on all parameters of the motion. Consequently, there is considerable variation among statements in the literature about the motion of the thoracic spine.

There are available at present two well developed and accurate biomechanical experimental methods to describe movement of rigid bodies. One method has been used effectively in the lumbar spine, the other in the cervical spine. The information offered by the two methods is similar, different and complementary. Thus, it was elected to employ them both in this investigation.

In view of the fact that the goal of this endeavour was to offer descriptive information about the mechanics of the thoracic spine, this summary of the results will begin with general descriptive remarks based on measurements and analysis of the data from both parts of the investigation. There is wide variation among the different subjects and different vertebrae of the same subject both in terms of quantity and quality of motion. Nevertheless, some general patterns emerge. There is *more flexion than extension*. One can expect 2-6° of motion at each interspace in the sagittal plane, 30-42% of which will be extension, the rest flexion. *At the lower thoracic levels, especially Th10 and Th11, there is relatively more sagittal plane motion.* Lateral bending is in the range of 3-6° at each interspace. No pattern of cephalocaudal variation emerged here. The total motion in this plane was found to be greater than for the sagittal plane. Axial rotation was in the range of 2-6° with the most caudal portion (Th10 and Th11) at the lower end of that range.

Other findings related to specific questions are also summarized here. This data did not show any correlation, positive or negative, between age and amount of motion. Tests of the relationship of the motion ratio (disc height/disc

This descriptive analysis of the normal thoracic spine includes some considerations of considerable clinical import especially in the field of traumatology. The characteristic patterns and ranges of motion for the different portions of the thoracic spine is of value in the interpretation of and the protection from offending forces. The same information assists in the recognition of those portions most likely to be susceptible to damage by forces of particular magnitudes and directions. Even more important perhaps is the complete mathematical description of three dimensional motion employing the helical axis of motion. The use of this thorough precise mathematical description in conjunction with the spring constant offers extensive possibilities. Examples would be the construction of representative mechanical models and the accurate mathematical prediction of expected behavior of the spine in response to normal and pathological forces.

The findings of this investigation of 27 autopsy specimens admit the following remarks about the thoracic spine. Its upper and lower portions behave quite differently and have certain traits suggestive of their neighboring adjacent regions of the spine. That portion of the spine between the two extremes is fairly homogenous in most of its characteristics none of which are particularly distinguishing. The main generalization that characterizes this region of the spine situated in the thorax is that it moves very little.

The analysis of the mechanics has been carried out and presented in a manner that can be meaningfully interpreted and employed by the biologist as well as the engineering scientist.

THE ARCHITECTURE OF THE TENDON

The tendon is a connective tissue structure composed of closely packed collagen fibers and protein mucopolysaccharide. The collagen fibers are as long as the tendon (Bucher 1962) and where they do anastomose with each other they do so at acute angles. The cell responsible for the elaboration of the collagen and the protein mucopolysaccharide and maintenance of the integrity of the tendon is the 'Tenocyte or fibroblast' (Hall & C. 1965). The collagen fibres are grouped together in primary bundles (Schneider 1959) which in turn are assembled into larger secondary bundles (Schneider 1959) or fascicles (Edwards 1946). The secondary bundles then form tertiary bundles (Schneider 1959) which together comprise the tendon. Tendons vary in length and in cross sectional area and the latter varies with the part of the tendon diminishing in a proximodistal direction. Edwards (1946) claims that if the secondary bundles or fascicles are considered as the unit structure of tendon then some uniformity exists. These fascicles are hexagonal in shape with a cross sectional area between 0.125-0.375 square millimeters.

The tendon bundles are surrounded by a woven mesh of loose connective tissue the peritenoneum internum or endotenon. This tissue holds the bundles together permits some movement of bundles with relationship to each other and carries all the blood vessels lymphatics and nerves. It has elastic fibres (Hirai 1959) which tend to draw the tendon bundles into a wavy formation when relaxed. At the musculotendinous junction there is an intimate relationship between the sarcomeres and the collagenous fibril bundles although no direct continuity exists (Boyd 1960). Electron microscopic studies have shown that the sarcolemma is intact at the junction and that the tendon bundles are invaginated into the ends of muscle fibers in the many terminal indentations of the outer sarcolemmal layer. In this way a considerable surface contact between the muscle fiber and the collagenous fibrils is achieved. Each group of muscle fibers enclosed in primary unit continues as a secondary bundle or fascicle and the peri-

mysium is continuous with the endotenon (Edwards 1946) This very regular arrangement does not hold true where muscle fibers join the tendon obliquely, but the general organization pattern is similar

At the tendo osseous junction the collagen fibers continue as the perforating fibers of Sharpey The endotenon becomes continuous with the periosteum but the cortical zone of the bone at the insertion of the tendon, as long as the cross sectional area of insertion is not large is free of periosteum (Schneider 1959)

The whole tendon is surrounded by a fine connective tissue sheath, the peritenoneum externum or epitenon, which is continuous throughout on its inner surface with the endotenon

Surrounding the tendon is a loose fatty areolar tissue, the paratenon (Smith 1965) Its mechanical function is to allow the tendon to glide freely against the surrounding tissue (Brind 1961, Stenmalmberg 1962) In areas where a tendon passes over a structure which might harm it that is zones of local pressure and friction, the paratenon is replaced by a synovial sheath or bursa and in the tendon in corresponding areas either cartilaginous plates or sesamoid bones may develop The visceral layer of this tenosynovium is dense fibro elastic and closely adheres to the epitenon (Edwards 1946) The visceral and parietal layers of the tenosynovium are continuous with each other at the ends of the tendon synovial sheath as well as through mesentery like structures the mesotendons which in some areas have been designated as vincula tendinum

THE BLOOD SUPPLY TO THE TENDON

The tendon is a well vascularized tissue The blood supply is less profuse than that of muscle but there is no tendon without a blood supply (Biesalski and Mayer 1916 Smith 1965)

A tendon receives its blood supply at the musculotendinous junction, along its length whether it be in paratenon or tendon sheath and in the region of its insertion

A The Musculotendinous Junction

There are a number of longitudinal vessels, both arterial and venous which traverse the musculotendinous junction (Wollenberg 1905 Arai 1907 Ray 1914 Dychno 1936 Edwards 1946) Most of these vessels run in the depth of the tissues The observation of Rau (1914)

that vessels which in youth cross the musculo tendinous junction in the depth later in life assume a superficial position has not been substantiated by subsequent investigators. Both Pau (1914) and Dychno (1936) made the observation that frequently one or two of these vessels appear as chief vessels and after crossing the musculotendinous junction traverse the full length of the tendon only to loop back on themselves at the musculo osseous junction.

Edwards (1946) pointed out that only the vessels in perimysium continue into the tendon but that the capillary circulation of the muscle and of the tendon is completely separate and distinct. The capillaries adjacent to the sarcomeres loop back at the musculotendinous junction to drain into the venules of the muscle and no capillary anastomoses exist at the junction of the two tissues.

In addition to this longitudinal system one frequently encounters smaller arteries and veins which divide near the musculotendinous junction with one branch joining the muscle and the other the tendon.

B The Paratenon

The paratenon contains many vessels which are largely responsible for the blood supply to the tendon (Wollenberg 1905 Arai 1907 Pau 1914 Dychno 1936 Edwards 1946 Smith 1965). At frequent intervals small vessels arise from neighbouring vessels and run transversely through the paratenon towards the tendon. On approaching the tendon the vessels may branch several times before assuming a direction parallel with the longitudinal axis of the tendon. It is at this point that they join the tendon circulation (Edwards 1946 Smith 1965).

C The Synovial Tendon Sheath

The synovial tendon sheaths have rich vascular nets on their surface as well as in their depths (Dychno 1936 Edwards 1946). These are more profuse in the areas of the pulleys (Smith 1965). The visceral layer of the tenosynovium receives a rich blood supply through the mesotendons as well as through its connections with the parietal layer at the ends of the synovial tendon sheaths (Edwards 1946). The mesotendons are nothing more than prolongations of the paratenon (Dychno 1936) although in this instance the paratenon is interposed between two layers of synovial tissue. As in the paratenon the number of vessels in a particular region varies. The circulation in the visceral layer of the tenosynovium (Edwards 1946. Observations made on the cow)

mysium is continuous with the endotenon (Edwards 1946) This very regular arrangement does not hold true where muscle fibers join the tendon obliquely, but the general organization pattern is similar

At the tendo osseous junction the collagen fibers continue as the perforating fibers of Sharpey The endotenon becomes continuous with the periosteum, but the cortical zone of the bone at the insertion of the tendon, as long as the cross sectional area of insertion is not large, is free of periosteum (Schneider 1959)

The whole tendon is surrounded by a fine connective tissue sheath the peritenon (externum or epitenon) which is continuous throughout on its inner surface with the endotenon

Surrounding the tendon is a loose, fatty, areolar tissue the paratenon (Smith 1965) Its mechanical function is to allow the tendon to glide freely against the surrounding tissue (Brand 1961 Stanisavljevic 1962) In areas where a tendon passes over a structure which might harm it, that is, zones of local pressure and friction the paratenon is replaced by a synovial sheath or bursa and in the tendon in corresponding areas either cartilagenous plates or sesamoid bones may develop The visceral layer of this tenosynovium is dense, fibro elastic and closely adheres to the epitenon (Edwards 1946) The visceral and parietal layers of the tenosynovium are continuous with each other at the ends of the tendon synovial sheath as well as through mesentery like structures the mesotendons which in some areas have been designated as vincula tendinum

THE BLOOD SUPPLY TO THE TENDON

The tendon is a well vascularized tissue The blood supply is less profuse than that of muscle but there is no tendon without a blood supply (Biesalski and Mayer 1916 Smith 1965)

A tendon receives its blood supply at the *musculotendinous junction*, along its length whether it be in paratenon or tendon sheath and in the region of its insertion

A The Musculotendinous Junction

There are a number of longitudinal vessels both arterial and venous which traverse the musculotendinous junction (Wollenberg 1905 Arai 1907 Ray 1914 Dychno 1936, Edwards 1946) Most of these vessels run in the depth of the tissues The observation of Rau (1914)

The architecture of the epitenon vessels is very variable. It is generally very profuse in areas where the tendon is in paratenon but varies not only from tendon to tendon but also in different areas of the same tendon. Certain areas of the epitenon have a highly characteristic and organized vascular architecture (Guse 1963, Winter 1965). No epitenon vessels are located on the side of the tendon which comes in contact with pulleys or where friction would be at its maximum (Smith 1963). An excellent example of this is the arrangement of the vincula tendinum on the dorsum, the nonfriction area of the tendons within a tendon sheath.

THE METABOLISM OF THE TENDON

A co relationship exists between the blood supply of a tissue and its metabolic requirements. The information on tendon metabolism however is very scanty. Neuberger (1953) measured a small but definite turnover of amino acids in the collagen of adult tendons and Peacock (1959) found the respiratory activity to be 0.1 microliters per unit weight per hour.

White (1964) has estimated the average rate of blood flow in tendon to be 0.10 cubic centimeters per gram per minute. The contentions of Berkenburch (1887) and Rau (1914) that the blood supply in tendon varies with age have found some confirmation in the experiments of Rothman (1965) who found that there is an apparent decrease in the capillary bed of a tendon with aging. More recently Rothman (1967) has also demonstrated that a significant decrease occurred in the capillary bed volume in tendon tissue following a six week period of immobilization.

THE INVESTIGATION

No intravital study of the microvascular anatomy and microcirculation of the tendon could be found in the literature.

All studies published to date have been carried out on dead specimens. The vessels of the tendons prior to study were usually filled with a contrast medium. The tendon was then in accordance with the technique employed suitably processed and examined microscopically or by angiography. Such an approach has certain obvious inherent draw

consists of a superficial capillary network and a much deeper plexus of arteries and veins. The capillaries loop to the surface from the underlying arterioles and venules. It is only the deep plexus which communicates with the tendon circulation" by short anastomotic channels.

D The Tendon Bone Junction

Wollenberg (1905), Arai (1907), Rau (1914), Dychno (1936) and Nichols (1954) were unable to demonstrate any direct communication between the tendon circulation and bone. They all describe anastomoses between the tendon vessels and periosteum. Only Edwards (1946) claims to have been able to demonstrate in some areas branches passing directly through to the cortical layers of bone but he also points out that these vessels are small, few and irregularly distributed.

The vessels in the tendon at its insertion anastomose with those present in the periosteum and only by means of this indirect communication have a connection with the osseous circulation.

The arrangement of the internal vascular architecture of the tendon is primarily one of longitudinally oriented blood vessels which run in the endotenon in the long axis of the tendon (Arai 1907, Biesalski and Mayer 1916, Dychno 1936, Edwards 1946, Braithwaite and Brockis 1951, Brockis 1953, Smith 1965).

According to Edwards (1946) these vessels are arteriolar in size with a well developed tunica media and are arranged around the fascicles. Accompanying each arterial channel are two veins, one on each side which communicate frequently with each other usually in the neighbourhood of a tributary or a branch (Edwards 1946, Brockis 1953). Dychno (1936) on the other hand, found only occasionally larger vessels. Most of the vessels he was able to demonstrate histologically were capillaries with a single endothelial lining.

The capillaries arise from the arteriolar branches, form loops which then drain into several venules. These loops may run from one longitudinal channel to another or back to the parent vessel. The capillaries are intra fascicular and do not penetrate the collagen bundles (Dychno 1936, Edwards 1946).

This internal vascular system is fed from the vessels present in the epitendon. Branches arise from the epitendon vessels and enter the tendon substance radially along the endotenon. These either anastomose directly with the longitudinal vessels or divide first into ascending and descending branches before doing so.

The architecture of the epitenon vessels is very variable. It is generally very profuse in areas where the tendon is in paratenon but varies not only from tendon to tendon but also in different areas of the same tendon. Certain areas of the epitenon have a highly characteristic and organized vascular architecture (Guse 1963, Winter 1965). No epitenon vessels are located on the side of the tendon which comes in contact with pulleys or where friction would be at its maximum (Smith 1965). An excellent example of this is the arrangement of the vincula tendinum on the dorsum, the nonfriction area of the tendons within a tendon sheath.

THE METABOLISM OF THE TENDON

A corollary relationship exists between the blood supply of a tissue and its metabolic requirements. The information on tendon metabolism, however, is very scanty. Neuberger (1953) measured a small but definite turnover of amino acids in the collagen of adult tendons and Peacock (1959) found the respiratory activity to be 0.1 microliters per unit weight per hour.

White (1964) has estimated the average rate of blood flow in tendon to be 0.10 cubic centimeters per gram per minute. The contentions of Berkenbusch (1887) and Pau (1914) that the blood supply in tendon varies with age have found some confirmation in the experiments of Pothman (1965) who found that there is an apparent decrease in the capillary bed of a tendon with aging. More recently Rothman (1967) has also demonstrated that a significant decrease occurred in the capillary bed volume in tendon tissue following a six week period of immobilization.

THE INVESTIGATION

No intravital study of the microvascular anatomy and microcirculation of the tendon could be found in the literature.

All studies published to date have been carried out on dead specimens. The vessels of the tendons prior to study were usually filled with a contrast medium. The tendon was then in accordance with the technique employed suitably processed and examined microscopically or by angiography. Such an approach has certain obvious inherent draw-

consists of a superficial capillary network and a much deeper plexus of arteries and veins. The capillaries loop to the surface from the underlying arterioles and venules. It is only the deep plexus which communicates with the tendon "circulation" by short anastomotic channels.

D The Tendon Bone Junction

Wollenberg (1905), Arai (1907), Rau (1914), Dychno (1936) and Nichols (1954) were unable to demonstrate any direct communication between the tendon circulation and bone. They all describe anastomoses between the tendon vessels and periosteum. Only Edwards (1946) claims to have been able to demonstrate in some areas branches passing directly through to the cortical layers of bone, but he also points out that these vessels are small, few and irregularly distributed.

The vessels in the tendon at its insertion anastomose with those present in the periosteum and only by means of this indirect communication have a connection with the osseous circulation.

The arrangement of the internal vascular architecture of the tendon is primarily one of longitudinally oriented blood vessels which run in the endotenon in the long axis of the tendon (Arai 1907, Biesalski and Mayer 1916, Dychno 1936, Edwards 1946, Braithwaite and Brockis 1951, Brockis 1953, Smith 1965).

According to Edwards (1946) these vessels are arteriolar in size with a well developed tunica media and are arranged around the fascicles. Accompanying each arterial channel are two veins, one on each side which communicate frequently with each other usually in the neighborhood of a tributary or a branch (Edwards 1946, Brockis 1953). Dychno (1936) on the other hand found only occasionally larger vessels. Most of the vessels he was able to demonstrate histologically were capillaries with a single endothelial lining.

The capillaries arise from the arteriolar branches, form loops which then drain into several venules. These loops may run from one longitudinal channel to another or back to the parent vessel. The capillaries are intra-fascicular and do not penetrate the collagen bundles (Dychno 1936, Edwards 1946).

This internal vascular system is fed from the vessels present in the epitendon. Branches arise from the epitendon vessels and enter the tendon substance radially along the endotenon. These either anastomose directly with the longitudinal vessels, or divide first into ascending and descending branches before doing so.

MATERIAL AND METHODS

50 young rabbits (2-3 months of age) weighing approximately one kilogram were employed in this investigation

Part I Microangiography and india ink injections

Microangiography was carried out as described by Lundskog and Branemark (1968). India ink injections were carried out with commercially available india ink diluted with normal saline in the ratio of 1:5 and then filtered six times through Munktell filter paper No. 3. No measurements of injection pressures were carried out. Before injection the animal was heparinized. Injections were carried out through the femoral artery, aorta and where special emphasis was placed on the front paw through a polyethylene canula inserted into the axillary artery. After perfusion with Micropaque® or india ink the animal was given an overdose of anaesthetic and then the whole animal was immersed in 10% formalin for 10 days.

Tendons subjected to microangiography were carefully prepared by micro-dissection to preserve the epitenon. Tendons injected with india ink were carefully dissected out preserving the paratenon, periosteum and muscle. The tendons were then cleared using the Spalteholz technique and while immersed in the clearing solution with the aid of the stereo dissecting microscope (Leitz) were carefully prepared with micro instruments to preserve the architectural pattern of paratenon and epitenon. Recordings were made with the Leitz Wetzlar camera using objectives 16 mm, 12.5, 25 mm, 13.5 and 63 mm 1:4.5 with variable intensity diffuse transillumination and variable diaphragm openings of the objectives to allow for adjustment of focal length and thus allow for different degrees of optical tissue penetrance.

Part II Intravital Microscopy

All animals were anaesthetized using intravenous urethane and were tracheotomized. An attempt was made to carry out the intravital observations under as ideal conditions as possible (Branemark 1959). All preparations were carried out using microsurgical techniques with the aid of variable magnification and filtered illumination with the infra red portion of the spectrum filtered out. Hemostasis was achieved either by application of saline soaked Spongostan® or with a micro diathermy unit (Branemark 1964).

backs. The accuracy of the study depends on the degree of successful filling of the microvascular system with the injection medium. An even greater disadvantage of these techniques is that they do not provide any information on the haemodynamics of the microcirculation. One can demonstrate a vessel but one must infer its function. The behaviour of the microvascular units during physiological function of the tissue they are in cannot be studied at all.

In recent years there has been an attempt to define the relative importance of the blood vessels reaching the tendon. Peacock (1959) on the basis of radioactive isotope (P^{32}) uptake concluded that "the blood vessels entering long tendons from the muscular origin and periosteal insertion are able to nourish only the proximal and distal third of the tendon. The intrinsic vessels in long tendons are not capable of nourishing the central third by anastomoses with vessels entering from either end. Circulation to the central third of long tendons is by intermediate segmental vessels entering through disorganized paratenon or a definite volar mesentery. Permanent disruption of the central blood vessels to normal tendons or mechanical prevention of post operative adhesions around free grafts, causes cellular death and eventual disintegration of collagen bundles." Smith in 1965 delineated the segmental nature of the blood supply more precisely. He stated on the basis of silicone rubber compound injections that the microcirculation in tendons is segmental in nature and that a tendon freed from its segmental blood supply will only survive over a distance of 1-2 cm from its intact circulation. This conclusion however was based on the mere demonstration of vessels without an assessment of their function.

The recent advances in intravital microscopy allow for analysis of tissues and cells to proceed at a resolving level of 0.5μ and some times even better (Brunemark 1966). Thus it is possible to observe simultaneously the microvascular system and the structure and function of the living tissue within which the microvascular system is found. It is possible to study the intricate and intimate relationship between capillary structure, capillary topography and flow pattern and how this structure and activity of the terminal vascular bed is organized to meet the metabolic needs of the tissue.

The present investigation was designed in two parts. Part one was devoted to an assessment of the accuracy of morphologic demonstrations of the microvascular system of the tendon by means of clearing techniques and microangiography. Part two was devoted to intravital observations on the microvascular anatomy and microcirculation of the tendon.

The lack of any uniformity in the vascular architecture of the epitenon circulation in different tendons and even in the same tendon was striking (See Fig. 4 and compare it with Fig. 2 and 3) Fig. 5 and Fig. 6 are segments of the same tendon showing an entirely different arrangement of the epitenon vascular architecture.

An attempt was made to analyze the relationship between the tendon mass and the spacial orientation of the vessels. In order to accomplish this we analyzed cross sections of thin flat tendons such as the extensor digitorum communis distal to the musculotendinous junction but proximal to the extensor retinaculum and thick round tendons such as the flexor carpi ulnaris. A definite correlationship was established. Thick round tendons in addition to their epitenon circulation have a number of vessels deeply situated in their substance (See Fig. 7, 8 and 9). In many instances it was possible to demonstrate the connections between the epitenon vessels and those in the substance of the tendon (See Fig. 9, 10 and 11). Thin flat tendons on the other hand have most of their vessels situated either in epitenon or very close to the surface in endotenon (See Fig. 12 and 13).

Part II Intravital Microscopy

A number of tendons were examined before the extensor digitorum communis was chosen as the experimental model. These trials will be discussed because observations made during the search for a suitable tendon and a suitable method are pertinent to the discussion. The first tendon to be examined was the tendo achilles. Although attempts at transillumination failed because of the thickness of the tendon under the dissecting microscope at a magnification of 80 \times we observed a very rich epitenon circulation characterized by very similar repeating microvascular units fed by separate arterioles and draining into separate venules. We transected the tendo achilles at its mid and lower third with a micro scalpel and used microdiathermy to control hemorrhage from the epitenon circulation. We found many punctate hemorrhages in the depth of both the proximal and distal stumps which confirmed the presence of vessels within the tendon.

The next tendon to be examined was the tibiialis anterior. In the rabbit the parietal tenosynovium surrounding the tibiialis anterior at the ankle forms a large sac and contains a considerable quantity of synovial fluid. The extensor retinaculum is in the form of a thick fibrocartilaginous band. We chose this tendon to avoid the problems

The exposed tendons were studied in the 'Leitz Intravital Microscope' using both transillumination and incident illumination. For incident illumination the Ultropak objectives UO \times 3.8 \times 6.5 \times 11 and \times 22 were employed. Photomicrographic recordings were made as described by Branemark (1963) and with certain modifications thereof.

RESULTS

Part I A Microangiography

Microangiography proved to be an unsuitable method for the demonstration of tendon microvascular architecture. In spite of constant perfusion conditions the filling of the vascular system with Micropaque was very variable. In addition the kV and mA required for uneven tissues, "burned out" in some areas any microvascular portion of the system that was filled. These tendons were subsequently cleared by the Spalteholz technique and examined. A very variable filling of the small vessels was observed with frequent 'embolic' phenomena. An attempt was made to use "Thorotrast" instead of Micropaque. Although the study was carried out only in one animal the necessity for immediate removal of the tendon with ensuing leakage of the 'Thorotrast' from patent vessels does not suggest great promise for this technique.

B India Ink Injections

With this method it was possible to achieve a much better filling of the microvascular system and more reliable studies could be accomplished. It must be emphasized, however, that despite filtering of the solution and heparinization of the animal when such a perfusion was observed under the intravital microscope frequent clumping with embolic phenomena occurred. This resulted in a variable filling of the microvascular system. Even if intravascular clumping of the particles did not occur then only those capillaries were filled which were open while the perfusion was being carried out. Therefore we did not attempt any detailed analysis of the microvascular system on the basis of this method. It was employed as a means of general survey of the vascular anatomy of the tendon in the rabbit.

The illustrations (Fig. 1, Fig. 2 and Fig. 3a, b) show that the vascular anatomy of the tendon in the rabbit conforms to the general pattern observed in man.

The lack of any uniformity in the vascular architecture of the epitenon circulation in different tendons and even in the same tendon was striking (See Fig 4 and compare it with Fig 2 and 3) Fig 5 and Fig 6 are segments of the same tendon showing an entirely different arrangement of the epitenon vascular architecture

An attempt was made to analyze the relationship between the tendon mass and the spiral orientation of the vessels. In order to accomplish this we analyzed cross sections of thin flat tendons such as the extensor digitorum communis distal to the musculotendinous junction but proximal to the extensor retinaculum and thick round tendons such as the flexor carpi ulnaris. A definite correlationship was established. Thick round tendons in addition to their epitenon circulation have a number of vessels deeply situated in their substance (See Fig 7 8 and 9). In many instances it was possible to demonstrate the connections between the epitenon vessels and those in the substance of the tendon (See Fig 9 10 and 11). Thin flat tendons on the other hand have most of their vessels situated either in epitenon or very close to the surface in endotenon (See Fig 12 and 13).

Part II Intravital Microscopy

A number of tendons were examined before the extensor digitorum communis was chosen as the experimental model. These trials will be discussed because observations made during the search for a suitable tendon and a suitable method are pertinent to the discussion. The first tendon to be examined was the tendo achilles. Although attempts at transillumination failed because of the thickness of the tendon under the dissecting microscope at a magnification of $80\times$ we observed a very rich epitenon circulation characterized by very similar repeating microvascular units fed by separate arterioles and draining into separate venules. We transected the tendo achilles at its mid and lower third with a microscalpel and used microdiathermy to control hemorrhage from the epitenon circulation. We found many punctate hemorrhages in the depth of both the proximal and distal stumps which confirmed the presence of vessels within the tendon.

The next tendon to be examined was the tibialis anterior. In the rabbit the parietal tenosynovium surrounding the tibialis anterior at the ankle forms a large sac and contains a considerable quantity of synovial fluid. The extensor retinaculum is in the form of a thick fibrocartilagenous band. We chose this tendon to avoid the problems

of the paratenon and hoped that in this fashion a segment of the tendon could be transilluminated with its internal vascular supply" intact. The synovial tendon sheath and the fibrocartilagenous extensor retinaculum were opened. The tibialis anterior was transilluminated with its insertion intact as well as transected at its insertion and lifted out of its bed. We again failed to visualize any internal vascular supply. This undoubtedly is related to the thickness of the tendon, the relatively poor contrast of living unstained tissues and the inability to penetrate optically a thick translucent tissue with the intravital microscope.

The surface of the tendon deep to the extensor retinaculum, was devoid of any vessels at the level of the ankle joint as this is a friction zone. A mesotendon reached the tibialis anterior on its posterior non friction surface. This afforded an opportunity to observe the circulation in the mesotendon as well as in the epitendon on that side.

The mesotendon contained vessels of the order of pre arteriolar arteries and small veins. The mesotendon was long and the vessels folded up in an accordion like fashion without any disturbance in the flow of blood. Stretching the mesotendon first produced a slowing of both the arterial and venous circulation and at greater tensions the circulation came to a standstill. On reaching the epitendon the arterial vessel divided into a central ascending and descending branch from which at regular intervals on both sides arose arterioles which in turn gave rise to capillary beds. Each capillary bed drained towards the central vessel via many venules which on reaching the center gave rise to one or two venous commitantes, one on each side of the arterial vessel. The capillary circulation had also many capillary anastomoses at its periphery joining each microvascular unit with its neighbour. Occasionally one could also see a branch of an arteriole dipping into the substance of the tendon.

The extensor carpi ulnaris was chosen as the next tendon. Because of its situation once the paratenon was stripped the tendon could be easily lifted out of its bed and by rotating the limb one could easily bring this tendon between the condenser and the objective of the microscope. This tendon was thin. There was no problem with transillumination or optical penetration of the tissue. Yet we failed to identify a single vessel except in the region immediately adjacent to the musculotendinous junction where the circulation appeared intact.

The extensor digitorum communis is a long flat tendon which only narrows and becomes round close to the extensor retinaculum. In its proximal portion immediately adjacent to the musculotendinous

junction to the naked eye it appeared as a single tendon. Under the dissecting microscope however, even at this level four discrete tendons thin and flat all enveloped in a glistening transparent paratenon could be identified. More distally the identity of each tendon become more obvious. These tendons are so arranged that in their proximal portion they slightly overlap each other with the most lateral (radial) one being most superficial.

A window was made in the lateral aspect of the paratenon and a prism 1 mm \times 1 mm and 3 mm in width attached to a fibre optic was introduced under the tendon. In this way transillumination of a tendon in paratenon could be achieved (See Fig 14)

Fig 14 Illustration of transillumination of a tendon with a fibre optic and prism

Only large arterioles and venules could be demonstrated. The circulation was obviously impaired. The preparation was very sensitive to the extent the paratenon had to be freed to allow for the introduction of the prism under the tendon and also to the stretching of the tendon over the edge of the prism. The prism was modified. A plexiglass rod was employed (See Fig 15). The end was ground to a flat disc 5 mm in diameter and 1 mm in height. In the center a groove was cut 3 mm

Fig 15 Illustration of transillumination of a tendon with a ground plexiglass rod

wide and $\frac{1}{2}$ mm deep. By manipulation the freed tendon was slipped into the groove and transilluminated. Again only arterioles and venules with grossly impaired circulation could be demonstrated. We observed, however, that in incident illumination with most of the paratenon intact, a rich capillary circulation was present in the tendon. This observation led to the development of our present experimental model.

The paratenon and perimysium were carefully removed by means of microdissection from the exposed surface of the tendon and muscle respectively, preserving every vessel. The specimen was examined in incident light illumination with the ultropak equipment (See Fig 16).

We observed long and tortuous vessels in the paratenon interposed between the deep fascia and the tendon as well as paratenon vessels which reached the tendon from the side and on its under surface. These paratenon vessels were both arterial and venous. The arterial vessels on reaching the tendon divided first into smaller vessels which then give rise to a capillary plexus (See Fig 17). Our area of observation was limited to the musculotendinous junction and to the flat portion of the tendon. Where the tendon became round and passed beneath the extensor retinaculum it was in tenosynovium and had no surface vessels present as this is a friction zone.

Fig 16 Illustration showing the method of intravital observation of the tendon circulation using incident illumination

A The Musculotendinous Junction

Observations carried out on the musculotendinous junction have disclosed the following (See Fig 5)

- (1) The microvascular architecture of the muscle and of the tendon differ not only in their pattern but also show no communication. The muscle capillaries run a straight course along the sarcomeres (See Fig 18) and where these join the tendon the capillaries loop back to rejoin the muscle circulation (See Fig 19)
- (2) There are a number of vessels which cross the musculotendinous junction. These vary in size are quite superficial and are both arterial and venous although the veins do appear to be predominant

B The Tendon in paratenon

There were a number of longitudinal vessels which ran in the long axis of the tendon. Unfortunately most of these were too deep to be resolved with any detail using incident illumination. Flow directions

Fig 15 Illustration of transillumination of a tendon with a ground plexiglass rod

wide and $\frac{1}{2}$ mm deep. By manipulation the freed tendon was slipped into the groove and transilluminated. Again only arterioles and venules with grossly impaired circulation could be demonstrated. We observed, however, that in incident illumination with most of the paratenon intact a rich capillary circulation was present in the tendon. This observation led to the development of our present experimental model.

The paratenon and perimysium were carefully removed by means of microdissection from the exposed surface of the tendon and muscle respectively, preserving every vessel. The specimen was examined in incident light illumination with the ultropak equipment (See Fig. 16).

We observed long and tortuous vessels in the paratenon interposed between the deep fascia and the tendon as well as paratenon vessels which reached the tendon from the side and on its under surface. These paratenon vessels were both arterial and venous. The arterial vessels on reaching the tendon divided first into smaller vessels which then give rise to a capillary plexus (See Fig. 17). Our area of observation was limited to the musculotendinous junction and to the flat portion of the tendon. Where the tendon became round and passed beneath the extensor retinaculum it was in tenosynovium and had no surface vessels present as this is a friction zone.

arrows

Indicate direction of flow in capillaries and venules

Fig. 1. Diagram showing the long loop capillary pattern in the brain

in these vessels were both proximal and distal, but on this basis alone it was impossible to conclude which was arterial and which was venous

Arterioles appeared in random fashion close to the surface of the tendon and gave rise to the following types of microvascular units

- (1) There were capillary loops which ran for long distances parallel to the tendon bundles then looped back, traversed an even longer distance again parallel to the tendon bundles before looping back again to join a venule. One arteriole gave rise to more than one capillary loop, and by focusing up and down, it was possible to discern that these were in different planes of the tissue (See Fig 20 and Fig 21)
- (2) There were regions where the microvascular architecture appeared to be less specialized and resembled that of the hamster's cheek pouch (See Fig 22 and Fig 23)
- (3) There were also regions where the capillaries were very short, ran a straight course and immediately joined a venule. This suggested that they may function as shunts

In all capillaries (See Fig 24), high flow velocities have been observed. The velocities were so great that erythrocytes could not be identified as discrete particles with visual observation. This suggested a flow velocity of at least 1.0–1.5 mm/sec. Reversal of flow in the capillaries has been observed as well as vasomotion.

We subjected the tendon circulation to a number of manipulations

Trans section of the Tendon at the Level of the Carpus

(1) Once the tendon was cut, it immediately assumed a wavy pattern but no observable changes took place in its circulation in the exposed region which was being continuously observed

(2) Trans section of the Tendon at its Musculotendinous Junction

This manoeuvre was associated with considerable hemorrhage. The circulation in many of the longitudinal vessels stopped but the regional capillary circulation except that immediately adjacent to the cut appeared unaffected

(3) Isolation of a Segment of Tendon by Proximal and Distal Trans section Maintaining the Paratenon Intact

Immediately following the trans section all circulation in the tendon often came to a stand still. In some areas pulsatile movement of the

arrows

Fig. 2. Diagram illustrating the single-loop capillary pattern in the endometrium.

blood column occurred. Within one to two minutes however most of the arteriolar, capillary, and venular circulation in the isolated segment of tendon was resumed often sluggishly at first, but it soon returned to its former vigour (See Fig 25)

(4) Trans section of the Tendon Distally and Application of Varying Degrees of Tension

As previously stated distal trans section had no influence on the circulation proximally. As greater and greater tension was applied changes could be observed. At first the venous circulation slowed down then the capillary, until finally flow ceased altogether. On releasing the tension the flow was immediately resumed.

(5) Tendon Lymphatics

We have attempted to repeat Edwards (1946) method of lymphatic channel demonstration. He cautioned that the preparation must be fresh to succeed. Our preparation was alive. We observed all the technical points, and yet failed to get a single preparation.

In addition methylene blue was deposited in the tendon distally in the hope that with time and exercise the dye would be taken up by the lymphatics. Up to six hours no dye was observed proximally in the tendon.

DISCUSSION

The literature abounds with the term 'The Blood Supply to Tendons' without regard to the tendon in question. Berkenbusch (1887) studied the flexor tendons within flexor sheaths. Rau (1914) based his observations on the infrapatellar tendon and the tendo achilles. Edwards (1946) studied the flexors and extensors crossing the metacarpals and metatarsals. Arai (1907), Dichro (1936) and Smith (1965) have studied the tendons in the whole extremities. Similarities do exist but it is only on similarities that generalizations can be based.

There are many variations in the arrangement of vessels even within a single tendon which have to be considered if a meaningful functional analysis of tendon circulation is to be established.

It is important to draw clear distinction between endotenon, epitendon, tenosynovium and paratenon because this not only gives precise anatomic localization but also identifies regions of the tendon subjected to different local mechanical situations which determine the manner of the

blood supply to the tendon. Thus in paratenon where the relative amplitude of displacement of the tendon in relationship to the immediately adjacent tissue the paratenon is negligible because the paratenon moves with the tendon vessels can reach the tendon in a random fashion where the relative amplitude of displacement of the tendon in relationship to the immediately adjacent tissue is great because the tissue is fixed such as a pulley, an a retinaculum or fibrous tendon sheath the blood vessels reach the tendon on its non friction side in a specialized structure the mesotendon. Although we have found the injection techniques not sufficiently accurate for the demonstration and study of the microvascular units they serve well for the demonstration of larger vessels and for the study of their spacial organization. On the basis of our injection studies we have demonstrated that the spacial organization of blood vessels of tendons is related to the size of the tendon. Thin flat tendons tend to have most of their vessels arranged superficially in epitenon whereas thick round tendons have both a superficial and a deeper internal blood supply. It is for this reason that we feel that the epitenon circulation cannot be divorced from the tendon circulation proper because it takes part in supplying the metabolic needs of the tendon. This superficial and deep arrangement of vessels also suggests that there must be a critical distance between a microvascular unit which is the metabolic exchange zone and the tenocyte or that there is a relationship between a specific mass of tendon tissue and the spacial orientation of the microvascular units. As yet we have been unable to define this relationship but feel that the concept of Edwards (1946) and Prockier (1953) of a simple uniform system of vessels throughout with frequent and regular cross anastomosis is a gross over simplification. We have demonstrated *in vivo* three types of microvascular units which are not evenly or constantly distributed. The function of the longitudinal intrinsic vessels still remains obscure. They are incapable of supporting long segments of tendon whether it is in paratenon or tendon sheath (Lotenza 1959, Peacock 1963, Smith 1965). We have not been able to observe any circulation in the longitudinal vessels of tendons completely stripped of their paratenon blood supply. In tendons with only partially disrupted segmental paratenon blood supply the circulation in the longitudinal vessels was impaired. In an isolated segment of tendon with the paratenon vessels intact the microvascular circulation was intact but the flow in the longitudinal vessels was interrupted. This would suggest that they may be only venous channels and for this reason of course are unable to maintain a tendon viable.

which has been isolated from its segmental arterial blood supply

The fact that the blood supply to tendon is segmental may have definite bearing on certain clinical therapeutic manoeuvres Branemark et al (1967a b), and Goldie (1967) showed that certain suspension media of cortico-steroids completely arrest capillary blood flow One of the authors (JS) has knowledge of two patients whose tendoachilles were injected for crepitant tenosynovitis Within two weeks the patients sustained spontaneous ruptures of their tendo achilles It is likely that local necrosis of the tendo achilles occurred and as this tendon has to withstand tremendous tensile stresses, it ruptured in the necrotic area

We have adequate data to dispel certain long held concepts in tendon surgery Hall (1965) writes There is some purpose in distinguishing between a tendon transfer in which vascularized tendon is moved from its normal point of attachment and inserted into an adjacent area and tendon transplant in which the whole tendon is made avascular

Every manoeuvre which separates the tendon from its segmental paratenon or mesotendon renders the tendon avascular This not only explains why adhesion formation occurs but also why blocking interposition substances are doomed to failure In tendon transfer sharp angulation point pressure and excessive tension must also be avoided for they embarrasses the tendon circulation

Intravital observations in incident light are limited to the superficial layers of tendon only Thus only the micro vascular units in the epitenon and in the most superficial layer of the tendon could be studied However as the epitenon circulation is part of the blood supply to the tendon and in thin flat tendons such as the one studied most of the vessels were disposed superficially we employed this technique as a biological window into the behaviour of the micro vascular system of the tendon

Our data on the micro vascular anatomy of the tendon is not adequate to allow for any further conclusions We have established an experimental model and have made certain preliminary observations

We are continuing our investigations and hope to present in the future a more comprehensive analysis of tendon circulation

SUMMARY

- 1 A review of the literature dealing with tendon circulation is presented
- 2 Different techniques for the study of tendon circulation are evaluated

- 3 A method for the intravital study of tendon circulation is presented
- 4 Conclusions
 - a) Injection techniques are not adequate for the study of the micro vascular units of tendon circulation
 - b) There must be a critical ratio between available micro vascular exchange surface area and mass of tendon tissue
 - c) The blood supply to tendons is segmental whether the tendon is in paratenon or tenosynovium
 - d) Any surgical manoeuvre which frees the tendon from its paratenon or mesotenon devitalizes that segment of the tendon
 - e) The possible relationship between spontaneous tendon rupture and corticosteroid injection is presented
 - f) The influence of tension and compression on the tendon circulation is evaluated

ACKNOWLEDGEMENT

The authors wish to thank professor Carl Hirsch Department of Orthopaedic Surgery University of Gothenburg Sweden for his interest suggestions and helpful criticism as well as the laboratory staff of the Laboratory of Experimental Biology Department of Anatomy Gothenburg Sweden

A METHOD OF MEASURING THE CHANGE IN COMPRESSION APPLIED TO LIVING CORTICAL BONE

INTRODUCTION

Continuously changing mechanical stress seems to be essential for the maintenance of the functional internal architecture of a bone. If a living bone is protected from functional stress osteoporosis may develop. The physiological range of forces which cause the bone to follow Wolff's law of adaption to functional demand is not known. There is much confusion about the effect of different kinds of load (dynamic or static) on bone. Relatively small dynamic pressure changes may engender bone resorption. These forces may be developed by a growing aneurysm for instance or by a foreign body anchored to bone undergoing passive movement (Perren et al). The effect of static load is not the same. Key and Charnley have shown that osteotomised cancellous bone fixed under static pressure will quickly unite by new bone formation.

Little however is known about the reaction of living cortical bone to different amounts of static load and what circumstances lead to a condition such as pressure necrosis (Rustizky). Rigid fixation of necessity depends on inducing areas of pressure* between bone and metal and between bone fragments. Since bone and metal have high moduli of elasticity even a small loss of bone due to pressure would instantly eliminate the pressure areas and thus result in loss of rigidity.

It seemed important therefore to determine how compression might decrease over a long period when a static load was applied to live cortical bone. For this purpose a system of load sensitive compression plates has been designed. The application of these to normal or osteotomised diaphyseal bone was intended to provide continuous or intermittent pressure recording over a period of several weeks. The object of this paper is to describe the construction of this plate, the technique of pressure recording and the information obtained from preliminary experiments.

It would have been attractive to use the ferromagnetic device of Willentegger and Straumann with the prospect of real telemetry but this presented difficulties due to tissue reaction to the material and the need to compensate for bending and torque.

MATERIAL AND METHOD

As figure 1 shows bone may be put under longitudinal compression by applying an internal fixation plate using a compression clamp (compressor). The amount of the axial compression of the bone is equal to the axial tension in the plate (Fig. 2) if weight bearing and muscle contraction are eliminated.

In the sequel we use the words pressure and compression synonymously although strictly speaking the word pressure should be reserved for a state of three dimensional hydrostatic pressure.

Fig 3

Fig 4

Fig 5

Fig 3—5 A small four hole AO plate is modified (Fig 3) providing it with a strain gauge compartment (Fig 4) to measure longitudinal stress in the plate. The plate is fixed to the bone as shown in Fig 5 using the compressor (Fig 1)

- 1 to permit recording of longitudinal stress in the plate
- 2 to permit stable internal fixation of two diaphyseal fragments produced by osteotomy or fracture
- 3 the device must be well tolerated by the tissues

The strain sensitive device in the plate (Fig 4) is constructed using strain gauges which alter their electrical resistance in proportion to forces applied in the long axis of the plate. The resistance changes of the strain gauges are measured by a special carrier frequency bridge (Peeke WE 6002 precision bridge or Tetric Indicator IT 1). Metallic foil strain gauges (Frischen MFS FG R = 120 Ohms $k = 2$) are preferred to semiconductor gauges as the latter are not yet considered sufficiently temperature stable.

or ASIF

Fig 1 The AO* compressor is used to apply the AO* plate under tension. The compressor is removed after driving home the middle screw on the right hand side of the fracture

Fig 2 Cortical bone is compressed longitudinally by an internal fixation plate applied under tension. The amount of traction in the plate equals the amount of compression of bone if external forces resulting from weight bearing or muscle contraction are avoided

A gauge plate has been constructed. It is a modification of the AO* plate as developed by M E Müller (Fig 3). The plate is made of type 316 L stainless steel of which the ultimate tensile strength is about $90 \text{ kp}^*/\text{mm}^2$ and the Young's modulus $19\,000 \text{ kp}^*/\text{mm}^2$. The original AO screw with standard thread and recessed head and made of the same material as the plate is used. The holes for the screws in the bone are drilled and tapped and the plate applied with the special compressor (Fig 1) exactly as described by M E Müller, Allgower and Willenegger. Located between the two middle screw holes of the plate (Figs 5 and 6) is a strain gauge compartment which is made of the same piece of metal as the plate. The gauge plate is constructed to satisfy the following requirements

* or ASIF

** $\text{kp} = \text{Kilopond} = \text{Kilogram force}$

4 Insulation

Any failure of insulation would shunt the strain gauges. Insulation defects may be asymmetrical thus imitating a change of the resistance of the gauge and thereby producing a false reading. To avoid such errors the resistance of the gauges versus the plate is measured regularly and plates with insulation defects are discarded.

5 Leads

Changes in the resistance of the leads would also imitate changes in the gauge resistance. By connecting the strain gauges within the plate to each other to form a Wheatstone bridge the system is much less sensitive to changes in the lead resistance.

To test the gauge mounting for possible creep a constant load of 100 Kp was applied to 6 plates and strain recordings were taken during 1 week. In one of these plates strain was recorded during 10 weeks.

To find out to what extent stress relaxation due to inelastic deformation of the plate or screw would affect the plate on bone system in 2 experiments a gauge plate was applied to a steel tube and an initial load near 100 hp was installed. Strain recordings were then taken during 8 weeks. From these recordings an upper bound on the amount of stress relaxation to be expected in the plate on bone system was estimated. The estimate was made from a simple model which included in an approximate way the effects of material and geometrical properties of the plate and the material beneath. A value for the Young's modulus of a sheep tibia was measured in a simple compression test and found to be 2100 kp/mm². The calculated rate of elongation of the gauge plate was 1μ/100 hp. On this basis the elastic deformation of bone was estimated to be between 10μ and 20μ depending upon the assumed stress distribution.

Before use each plate was tested in a special machine (Fig. 8a). The testing procedure included the following steps:

1. The relation between measured strain and axial load was plotted over a range from 0—100 hp (Figs. 8a, 9 and 10).
2. The influence of temperature was tested in a saline bath at temperatures of 27°, 37° and 47° C (Figs. 8a and 9).
3. The influence of bending and torque was measured applying a constant moment of 20 cm · hp (Figs. 8d, 8e and 10).
4. The insulation of the gauges was tested and plates with an insulation resistance < 10⁶ Ohms were discarded.

Fig. 7 The load cell contains 4 strain gauges forming a Wheatstone bridge which compensates for temperature and bending influences. The gauge plate is connected to a carrier frequency amplifier which drives a recorder.

Fig 6 The load cell incorporated in the plate permits continuous recording of longitudinal traction in the plate and thus measurement of compression in the osteotomy

When using strain gauges in such a load cell care must be taken to

- 1 compensate for temperature changes
- 2 prevent plastic deformation of the load cell
- 3 compensate for bending moments
- 4 ensure good insulation
- 5 prevent errors due to resistance changes in the electrical leads

1 Temperature

Temperature changes affect the strain readings due to

- a) thermal expansion of the underlying metal
- b) thermal changes in the resistance of the gauges

Thermal expansion of the underlying material may be easily compensated for by the use of appropriate gauges. Temperature effects on the gauges' resistance may be compensated for by the use of twin gauges which are both at the same temperature level but only one of which is under strain. In the present system temperature compensation is achieved by the use of a pair of identical gauges one of which is in the long axis of the plate the other at 90° to it.

2 Deformation

The relationship between stress and strain is linear only if the metal beneath the gauges is stressed within its own elastic limits. To prevent any overload due to bending and torque the chamber is provided with weekend segments to prevent plastic deformation of the load cell (Fig. 4).

3 Bending

There remains a possibility of some elastic deformation by bending. Two pairs of temperature compensated strain gauges are located equidistant from the neutral axis of bending. They are connected to a Wheatstone bridge circuit the balance of which is affected only by axial forces acting on the load cell and not by temperature changes or bending forces. This arrangement is simpler to achieve than using one pair of strain gauges placed exactly in the neutral axis of bending (Figs 5—7).

8c

Fig 8d

Fig 8e

Fig 8c The gauge plate is mounted with the use of two clamps

Fig 8d Calibration of indicated strain versus torque (20 cm Kp)

Fig 8e Calibration of strain versus bending A constant moment over the whole length of the plate is applied (20 cm Kp)

RESULTS

The curve made by plotting axial force against measured strain is shown in figure 9. In the same figure the error due to temperature changes is also plotted. The calibration curve is linear and the influence of temperature is small.

The errors due to bending forces in two directions and due to torque are indicated in figure 10. The influence of these forces is negligible.

The strain re-ordering of the plate with a constant load acting demonstrated that the creep of the strain gauge mounting was very small.

Fig 8a Test rig shown ready to calibrate indicated strain versus longitudinal traction at different levels of temperature. The gauge plate placed in a temperature controlled bath of saline is loaded by the use of a Jack Screw. The applied load is measured with a dynamometer (Fig 8b) while the precision bridge at left permits reading of indicated strain.

Fig 11 Estimated change of compression in the bone due to inelastic deformation of the plate and the screws

Fig 12 Pressure recording with gauge plates on sterile dead bone at 37°C and high humidity. Note the initial fall of pressure due mainly to viscoelastic properties of bone

Figure 11 shows the estimated change of compression in the bone due to inelastic deformation of the plate and screws. On the basis of a simplified model of the system, this deformation was estimated to be less than 0.2%.

Figure 12 shows the decrease of compression in intact dead bone in a temperature controlled environment of high humidity. Here an initial steep decrease is followed by a very slow decrease. The total loss of compression over 8 weeks is of the order of 20% of the initial value.

DISCUSSION

The gauge plate has proved to be useful in recording the change of axial compression of bone. In preliminary experiments the strength of the plate and the tissue tolerance were found to be adequate. Very little creep has been encountered in the strain gauge mounting. Furthermore the experiment with plates on steel tubes revealed little stress relaxation due to inelastic deformation of the plate and the screws.

The experiment using freshly removed tibiae has shown a decrease of the order of 20% which cannot be accounted for by biological processes. This decrease occurs in the first few days and is followed by no appreciable long term decrease. It most likely results from the viscoelastic properties of bone itself (Sedlin).

Fig 9 Calibration curve plotting applied load versus indicated strain at different temperatures. The relation is linear and the temperature influence small. The strain is expressed in $\mu\text{m/m}$.

THE REACTION OF CORTICAL BONE
TO COMPRESSION

by

S M Perren A Huggler M Russenberger M Allgöwer
R Mathys R Schenk H Willenegger and M E Müller

with the technical assistance of V Geret and E Frey

In the «plate on bone» system a total load of 100 kp results in an elastic deformation of only 10—20 μ . Since small changes in the length of the system will result in large changes in force the gauge plate is suitable for measuring the small changes in bone length which might be caused by creep resorption or failure of fixation.

As a whole the method now seems to be ready for use in living animals. Results on the behaviour of intact living bone and osteotomised living bone will be reported below.

SUMMARY

The reaction of bone to compression is of primary importance in the internal fixation of fractures. Any induction of «pressure necrosis» and consequent bone resorption would result in total loss of rigidity. A gauge plate has been developed to study *in vivo* the reaction of bone to compression by recording the change of load in the bone with time. The method permits detection of minute changes in bone length due to creep resorption or instability. It is therefore a valuable tool for investigating the quality of a fixation over extended periods of time.

THE REACTION OF CORTICAL BONE TO COMPRESSION

INTRODUCTION

Rigid internal fixation by necessity depends on the production of local pressure areas between implant and bone or between bone ends. Wherever pressure necrosis and consequent bone resorption occurs there will be a loss of stability. It is vital therefore to understand precisely the reaction of bone to static compression*.

Clinical experience shows that bone can withstand a considerable static load without pressure necrosis becoming apparent (Lambotte, Davis, Lane, Hicks, M. E. Muller, Allgower and Willenegger). Quantitative information however is lacking about the type and magnitude of forces which will promote functional adaptation of bone structure to stress according to Wolff's law.

There are two ways of measuring the change in pressure applied to bone. One employs a system with a comparatively high deformability while the other uses a system of very low deformability.

- In highly deformable systems the use of ordinary springs permits the determination of load continuously (Burri) or at the beginning and at the end of the experiment (Friedenberg & French). This method cannot detect small amounts of bone resorption as compression depends mainly on the deformability of the spring rather than of the bone. Furthermore such a system can become unstable at low pressures.
- In systems of low elastic deformability load sensitive metal plates are fixed to the bone. Here the deformability is infinitesimal compared with systems using springs. These systems thus are able to detect small changes in bone length due to e.g. creep or resorption.

Straumann designed a measuring plate that employed ferromagnetic material and this was used in animals by Willenegger. Telemetric readings of tension acting on such a plate were obtained by inserting the limb into a magnetic field. Accurate measurements were difficult however because of the effects of torque and bending and precise positioning of the plates in the magnetic field was impossible when using living animals. The ferromagnetic materials hitherto available also corroded badly in the tissues.

In view of these facts a four hole AO** compression plate of M. E. Muller's design was modified to incorporate strain gauges and thus to act as a compression plate and load cell at the same time. This plate allowed long term pressure recordings to be made unaffected by temperature changes and bending stresses. The plate itself was well tolerated by the tissues. Its precise specifications have been described above (p. 14).

In the sequel we use the words pressure and compression synonymously although strictly speaking the word pressure should be reserved for a state of three dimensional hydrostatic pressure.

THE REACTION OF CORTICAL BONE TO COMPRESSION

INTRODUCTION

Rigid internal fixation by necessity depends on the production of local pressure areas between implant and bone or between bone ends. Wherever pressure necrosis and consequent bone resorption occurs there will be a loss of stability. It is vital therefore to understand precisely the reaction of bone to static compression*.

Clinical experience shows that bone can withstand a considerable static load without pressure necrosis becoming apparent (Lambotte, Davis, Lane, Hicks, M. E. Müller, Allgower and Willenegger). Quantitative information however is lacking about the type and magnitude of forces which will promote functional adaptation of bone structure to stress according to Wolff's law.

There are two ways of measuring the change in pressure applied to bone. One employs a system with a comparatively high deformability while the other uses a system of very low deformability.

- In highly deformable systems the use of ordinary springs permits the determination of load continuously (Burtt) or at the beginning and at the end of the experiment (Friedenberg & French). This method cannot detect small amounts of bone resorption as compression depends mainly on the deformability of the spring rather than of the bone. Furthermore such a system can become unstable at low pressures.
- In systems of low elastic deformability load sensitive metal plates are fixed to the bone. Here the deformability is infinitesimal compared with systems using springs. These systems thus are able to detect small changes in bone length due to ϵ , g , creep or resorption.

Straumann designed a measuring plate that employed ferromagnetic material and this was used in animals by Willenegger. Telemetric readings of tension acting on such a plate were obtained by inserting the limb into a magnetic field. Accurate measurements were difficult however because of the effects of torque and bending and precise positioning of the plates in the magnetic field was impossible when using living animals. The ferromagnetic materials hitherto available also corroded badly in the tissues.

In view of these facts a four hole AO** compression plate of M. E. Müller's design was modified to incorporate strain gauges and thus to act as a compression plate and load cell at the same time. This plate allowed long term pressure recordings to be made unaffected by temperature changes and bending stresses. The plate itself was well tolerated by the tissues. Its precise specifications have been described above (p. 14).

In the sequel we use the words pressure and compression synonymously although strictly speaking the word pressure should be reserved for a state of three dimensional hydrostatic pressure.

** or ASIF

It is the purpose of this paper to report the reaction of the living tibial diaphysis of the sheep to known amounts of pressure load comparing the normal to the osteotomised tibia. Changes in load are the main demonstration of physical alterations occurring in the bone and are related to the histological appearance.

MATERIAL AND METHOD

To apply static compression to the bone four hole plates with built in strain gauges were used as described previously (p 9). The gauge plate compensated for bending moments and temperature variations gave either continuous or intermittent recordings. The plates were applied under tension to exert compression as described by M. E. Müller, Allgower and Willenegger.

Sheep 2—4 years old were used as experimental animals. They were anaesthetised with Fluothane¹⁾ (Hutzschenreuter & Perren). The tibia was approached from the medial side preserving the proximal nutrient artery. When the tibia had been exposed subperiosteally the gauge plate was fixed to the bone. The electrical leads were brought through the skin above the femoral trochanter to prevent retrograde infection. One of two procedures was then followed.

In 6 sheep of group A the plate was applied to the intact bone while in 9 sheep of group B an osteotomy was performed using a very fine saw that cleanly removed 0.1 mm of bone (Willenegger et al.). Continuous irrigation with Ringer's solution and slow movements of the saw prevented any thermal damage. To prevent splitting of the bone during osteotomy a special bone clamp was used. As the operated leg of the animal takes full weight soon after the operation two plates were applied at right angles to each other.

At the end of the operation the wounds were irrigated with Polybactrin²⁾ (solution containing Bacitracin, Neomycin and Nebacetin) and the skin closed with one layer of 4—0 dermalon³⁾ sutures using Allgower's technique. The suture was then protected by Nobecutan⁴⁾ spray and no dressing was applied. Negative pressure drainage was maintained for 24 hours using a disposable vacuum generator (Protevac⁵⁾) attached to the animal.

The amount of strain placed on the plate was measured while the compressor was being tightened until the required level was reached. The first base line reading was taken no sooner than 3 hours after operation to ensure that temperature equilibrium had been reached and the initial stress relaxation of bone had diminished.

Pressure readings were taken as described above (p 9). A few animals were followed continuously but in most of them recordings were made at weekly intervals. X rays^{*} were taken in *ap* and lateral projections every three weeks.

The sheep were kept as long as measurements were technically possible and were sacrificed only when the leads broke which in group B (osteotomised tibia) occurred between 3 and 12 weeks after operation while in the group A (intact tibia) breakage occurred between 7 and 12 weeks. In some animals not listed here measurements after 16 weeks were possible. Specimens were removed and embedded in Acrylic after fixation with 40% alcohol and staining with alkaline

Fuchsin. The bone segments were then cut into thin slices and ground to 50 without decalcification. All animals had received 500 mg of Aureomycin®) intravenously at various intervals after operation and remodelling of the bone could be studied by fluorescent microscopy.

It must be emphasized that many preliminary experiments were required to define long term measuring techniques in live animals. Difficulties arose from failure of insulation, retrograde infections and bending deformations in some early gauge plates. Animals with any of these failures are excluded from this report whereas on occasion of broken leads the animals were sacrificed but the results are included.

RESULTS

The pressure readings in group A (intact bone) are shown in figure 1. There is a gradual decrease of pressure over 12 weeks after a somewhat steeper decrease in the first few days.

Fig. 1 Pressure recording of group A where the plate was applied to intact bone. The pressure decreases gradually over 12 weeks after a steeper initial fall.

Fig. 2 Pressure recording in group B where the tibia was osteotomised. The rate of change of pressure is similar with or without osteotomy (fig. 1).

Fig 3 X ray taken immediately after operation The positioning of the two plates placed at right angles may be seen bridging the transverse osteotomy of the tibia

Fig 4 X ray taken at 10 weeks after operation In spite of full weight bearing very little callus can be seen Bony union has occurred

Fig 5 Histology of the cortex beneath the plate 12 weeks after operation Primary fracture healing is seen in spite of full weight bearing No specific resorption of the compressed surfaces is visible

Fig 6 Histology of the opposite side to the plate The gap between the fragments is first filled by lamellar bone (transverse osteon) which in turn will be remodelled later in axial direction Fluorescent label given 3 weeks after operation is found in such a transverse osteon The animal was sacrificed at 12 weeks

The pressure readings in group B (osteotomised bone) are shown in figure 2. The same initial decrease of pressure as in intact bone is seen. After this initial decrease the rate of change of pressure is similar to the one in intact bone. The rate of decrease of pressure does not depend on the initial level of pressure.

Typical radiographs of an osteotomised tibia are shown in figures 3 and 4. In figure 3 the transverse osteotomy of the tibia is seen fixed by two gauge plates. A part of the wire connection between the implanted gauge plate and the measuring bridge outside the animal is visible.

In figure 4 the radiograph taken 10 weeks after the operation shows the osteotomy gap bridged directly by bone while no external callus is seen in spite of early full weight bearing.

The histology of the specimen removed 12 weeks after osteotomy is shown in figure 5. It confirms the X ray finding of «primary bone healing». In no case is there any development of interposed fibrous tissue or cartilage. This shows that in spite of full weight bearing the osteotomy is bridged by direct Haversian remodelling. It can be seen that in the cortex which is in contact with the plate the new bone spanning the osteotomy is formed mainly in the long axis of the tibia. In the osteotomy of the cortex opposite to the plate the osteons are first laid down transverse to the long axis of bone but later remodelling takes place in the long axis as in the other cortex. The tetracycline label administered three weeks after operation is found in the transverse osteon (Fig. 6).

DISCUSSION

After application of compression there is no sudden drop of pressure. This statement applies to intact as well as to osteotomised bone under compression of 60–140 k μ p. The system is sensitive to very small changes in length (a few micra) and the pressure would have decreased to zero if there had been a loss of substance of 10–20 μ due to resorption. This resorption could occur either at the compressed interfaces of the osteotomy (Fig. 7a) or of the screw thread (Fig. 7b). Minute changes of length due to instability would also cause sudden changes of pressure (Fig. 7c).

The data indicate that at pressure levels of group A (intact bone) and B (osteotomised bone) namely at pressure levels of 60–140 k μ p no «pressure necrosis» is present. If a layer of bone as thin as 2–3 red cells disappeared at the compressed bone surface a complete loss of compression would result. In fact resorption of the compressed interfaces is not even observed at the small area of compressed bone at the screw site where a total pressure of 140 k μ p results in a specific pressure exceeding 400 k μ /cm. Regardless of the initial pressure there is an identical rate of change.

From the results it is reasonable to conclude that rigid fixation was maintained since any movement of the two fragments (even in the range of a few micra) would have resulted in a sudden change of pressure and most probably in a complete loss of compression. The fact that the pressure recordings permit conclusions about long term stability of fixation has interesting potentialities in testing new devices for internal fixation (see p. 45).

Fig. 2 The effect of various forms of bone resorption and instability on applied pressure in internal fixation. Minute amounts of bone resorption at the compressed bone surface either at the osteotomy (A) or at the screw thread (B) would lead to a steep fall of pressure. By a similar mechanism minute amounts of instability (C) would result in a sudden change of pressure. Longitudinal resorption of bone (Haversian remodelling) explains the slow and gradual fall of pressure (D) as seen in our experiment (Fig. 1 and Fig. 2).

The pressure readings in group B (osteotomised bone) are shown in figure 2. The same initial decrease of pressure as in intact bone is seen. After this initial decrease the rate of change of pressure is similar to the one in intact bone. The rate of decrease of pressure does not depend on the initial level of pressure.

Typical radiographs of an osteotomised tibia are shown in figures 3 and 4. In figure 3 the transverse osteotomy of the tibia is seen fixed by two gauge plates. A part of the wire connection between the implanted gauge plate and the measuring bridge outside the animal is visible.

In figure 4 the radiograph taken 10 weeks after the operation shows the osteotomy gap bridged directly by bone while no external callus is seen in spite of early full weight bearing.

The histology of the specimen removed 12 weeks after osteotomy is shown in figure 5. It confirms the X-ray finding of «primary bone healing». In no case is there any development of interposed fibrous tissue or cartilage. This shows that in spite of full weight bearing the osteotomy is bridged by direct Haversian remodelling. It can be seen that in the cortex which is in contact with the plate the new bone spanning the osteotomy is formed mainly in the long axis of the tibia. In the osteotomy of the cortex opposite to the plate the osteons are first laid down transverse to the long axis of bone but later remodelling takes place in the long axis as in the other cortex. The tetracycline label administered three weeks after operation is found in the transverse osteon (Fig. 6).

DISCUSSION

After application of compression there is no sudden drop of pressure. This statement applies to intact as well as to osteotomised bone under compression of 60–140 kP. The system is sensitive to very small changes in length (a few micra) and the pressure would have decreased to zero if there had been a loss of substance of 10–20 μ due to resorption. This resorption could occur either at the compressed interfaces of the osteotomy (Fig. 7a) or of the screw thread (Fig. 7b). Minute changes of length due to instability would also cause sudden changes of pressure (Fig. 7c).

The data indicate that at pressure levels of group A (intact bone) and B (osteotomised bone) namely at pressure levels of 60–140 kP no «pressure necrosis» is present. If a layer of bone as thin as 2–3 red cells disappeared at the compressed bone surface a complete loss of compression would result. In fact resorption of the compressed interfaces is not even observed at the small area of compressed bone at the screw site where a total pressure of 140 kP results in a specific pressure exceeding 400 kP/cm. Regardless of the initial pressure there is an identical rate of change.

From the results it is reasonable to conclude that rigid fixation was maintained since any movement of the two fragments (even in the range of a few micra) would have resulted in a sudden change of pressure and most probably in a complete loss of compression. The fact that the pressure recordings permit conclusions about long term stability of fixation has interesting potentialities in testing new devices for internal fixation (see p. 45).

most of the load to the quadrant of bone between the plates and much less to the opposite one

Nevertheless the highest stress of the order of about 400 kp/cm is found at the screw sites and still there is no evidence of pressure necrosis. This finding is in line with that of Charnley who found it unlikely that necrosis at a pressure level of 3000 lbs/sq inch (~ 210 kp/cm) would occur. The pressure within the range studied by us leads to a slow loss of load due to Haversian remodelling. If Haversian remodelling takes place at any cross sectional area in the compressed segment the pressure will decrease.

The data obtained clearly shows that static compression does not necessarily induce pressure necrosis. It seems probable that motion (which may be regarded as being intermittent pressure reaching zero level) does induce bone resorption (Perren et al) which may also be induced by infection. The observed slow decrease of compression in the present experiment is due to remodelling.

SUMMARY

A new gauge plate was used to study the change of compression applied to intact and osteotomised sheep tibiae. No steep fall of compression was seen indicating that there is neither pressure necrosis nor instability of fixation. A correlation between the slow decrease of pressure and the rate of Haversian remodelling has been established for intact and osteotomised bone. In spite of unrestricted weight bearing primary fracture healing was seen.

The second observation is the slow but continuous reduction of the pressure in the intact as well as in the osteotomised tibiae. When the gauge plates are fixed to a steel tube there is an initial pressure drop which when corrected for bone would be about 2%. On dead bone there is a loss of about 20% of the originally applied load (see p. 15) occurring mainly in the first week probably due in part to viscoelastic behaviour of the bone (Sedlin). A pressure loss above 20% should therefore be attributed to the response of living bone reacting to load conditions. The pressure does in fact fall to 50% within 2 months and the experiments which could be followed over a longer period indicated a further decrease of pressure reaching a new equilibrium near zero in 3–5 months.

The similar decrease of pressure in intact as well as in osteotomised bone indicates that the rate of change of pressure does not depend on any specific change peculiar to the osteotomy. This striking conclusion is based furthermore on the fact that the pressure recordings exclude any movement at the compressed surface of the osteotomy and that the histology (Fig. 5) does not show any surface resorption of the compressed area.

The histology gives a clue to the decrease in the compression force. It shows an intense Haversian remodelling of the compressed tibia. In their work on the dog radius Schenk and Willenegger noticed a remodelling rate of 60% within 8 weeks of osteotomy. This seems to be of the same order as that of the sheep though this animal seems to remodel at a slower rate than the dog. The physical effect of this process is the destruction of the osteons under pressure thus reducing the load bearing area of the compressed diaphysis (Fig. 7d). The loss of compression is not a linear function of the remodelling rate because the newly formed osteons will be loaded again when further osteons disappear. The fact that about 50% of the load has disappeared 2 months after loading would correspond well with Schenk's observation that at this time 60% of the osteons were remodelled.

Is living bone able apart from Haversian remodelling to alter its elasticity (as might occur by the direct dissolution of calcium apatite)? This cannot be answered from our experiment. In view of the obvious effect of Haversian remodelling such a mechanism seems to be neither necessary nor likely.

This work shows that a static preload of 60–140 kp on a cortical bone segment about 5 cm in length and between 1.5 and 2.0 cm in diameter does not induce rapid pressure necrosis. An osteotomy in this segment *in vivo* does not appreciably alter its response to static pressure as long as it is rigidly fixed. It is worth noting that «pressure necrosis» at this interface is absent and direct bridging occurs.

Two relatively short plates applied at right angles were used in our experiments as immediate weight bearing might have thrown a bending stress on a single plate. The disadvantage of too much «stress protection» of the plated part of the bone had to be accepted (Double plating in human fractures is rarely indicated and only then at the epiphyseal area of long bones). Two plates may prevent the major action of physiological stress and result in bone resorption prevailing over bone formation. In our experiment this effect seems to be partly offset by the comparative shortness of the plate and by the early weight bearing.

Expressing the value of pressure per unit of area is not felt justified as the distribution of load is not uniform. Plates applied at right angles would transmit

A DYNAMIC COMPRESSION PLATE

INTRODUCTION

Compression fixation of fractures and osteotomies has gained wide acceptance in recent years. Danis was probably the first to design a rigid longitudinal compression system using a plate screwed to the bone cortex and compressed by a device incorporated in the plate. Using this technique Danis was successful in securing radiological primary bone healing in fractures of the forearm bones and of the tibia. The application of such a plate however is not without its difficulties. As no advantage is gained by leaving the compression device in situ M. E. Müller has devised a separate compressor (see p. 8) which can be removed after the plate has been fixed to the bone. The use of rigid plates of various sizes combined with the removable compressor has been widely tested by the AO* group and has become known as AO* compression plate technique**.

The effect of known values of different static loads on intact as well as osteotomized diaphyseal bone has been thoroughly studied (p. 17). A tension force of 60–140 kp exerted on a rigid AO* plate will apply a corresponding compression force to the underlying cortical bone. It has been shown that under these conditions a resorption of 10–20% at the interface of an osteotomy or at the screw sites would result in an immediate abolition of the compression force (Perren et al., see p. 25). No such phenomenon was observed. On the contrary, well apposed osteotomy surfaces in dogs and sheep united directly by a process of simultaneous resorption and osteogenesis in the axial direction. There was however a gradual decrease from the initial load over the course of 3–5 months until a new equilibrium near zero pressure was reached. This gradual decrease in compression was matched by the histological finding of longitudinal Haversian remodelling of the cortex. The use of this compression type plate has been evaluated by experimental work on dogs (Schenk and Willenegger, Anderson, J. Müller) and sheep (Perren et al., see page 23). It has also been successfully applied to clinical cases, especially for fractures of the forearm and tibia as well as for non-unions (Anderson, J. Müller, M. E. Müller, Allgöwer and Willenegger).

The rigid compression plate with a separate compressor has some minor limitations:

1. after removal of the compressor there is an unpredictable change in the forces exerted by the screws inserted in the conical holes of the plate. Very small displacements of the screw in the plate can result in large pressure changes. Such a pressure change will occur if a screw is placed in a conical countersink with even a small amount of eccentricity.

* or ASIF

It should be emphasized that compression is not confined to the use of plates nor is compression always applied in the long axis of the bone. Wherever large and comminuted fractures are bridged by plates, compression is first exerted in a plane perpendicular to the fracture by screws crossing this plane.

Fig 2A—E The osteotomy or fracture is compressed when the screw is driven home from the position A—C Gliding movement is possible from position D Position A results in a horizontal displacement of 1.5 mm (3 mm total if both sides are used in this position) This position is scarcely ever necessary and will not be discussed further Positions B and C result in less displacement and less compression Position D final position offers optimum stability with three dimensional contact Position E at the end of gliding movement should be avoided

the closure of the fracture During all these movements the screw will be maintained in optimal lateral stability which could not be achieved by previous slotted plates

- b) the countersunk part of the screw (screw seat) was made spherical to fit the cylindrical shape of the screw hole
- c) the Young's modulus of the plate was decreased so that more functional stress could be transmitted to bone According to Wolff's law a more normal bony structure would then result To provide the desired elastic properties and good corrosion resistance of the plate (Hoar and Mears Steinemann) titanium was chosen

Oval compression holes and plates with slots have been used before Eggers devised his sliding plate to prevent deleterious gaps between the fracture surfaces His own studies however using telerradiology showed that the bone ends rarely slid together These plates did not regularly function as hoped because by the absence of a proper countersink fitting between the screw and plate adequate stability was achieved only by eliminating the gliding movement

Bagby modified a Colison plate so that a conical screw head sinking into a screw hole against a straight edge could close an osteotomy gap Tightening the screw automatically pushed the screw towards the fracture or osteotomy resulting in adaption of the bony surfaces He concluded that wherever good contact of osteotomised surfaces was present together with rigid fixation union occurred regardless of the amount of compression present However he rightly pointed out that compression increases stability In the present work a shape of screw hole was developed which retains the desirable compression and in addition offers the optimal lateral stability that was considered to be improvable in Bagby's design

Oblique screws do not achieve similar compression since once the plate is in contact with bone seating an oblique screw will not result in any displacement of the plate relative to the bone

The new plate which is described in detail on page 32 offers definite advantages over the well tested AO* plate provided that rigidity is maintained This is synonymous with maintenance of applied load

The purpose of the present paper is to outline the construction of and to report results obtained with titanium plates similar to those mentioned above These plates were modified by fitting them with strain gauges to measure compression forces in the osteotomy and thus to monitor the stability of fixation

* or ASIF

- 2 the removal of stress influences the bone beneath a rigid plate and can lead to some osteoporosis in the cortical bone. This has been observed in plate fixation of femora and tibiae especially when two and/or massive plates were used. When such plates are removed fatigue fractures may occur through the porous cancellous bone.
- 3 applying a separate compressor requires a wider exposure which may be difficult at some sites
- 4 the close conical fit between screw neck and plate countersink holds the screw at right angles to the plate. This may make it difficult to place the screw in exactly the right relation to a fracture line
- 5 there may be significant corrosion of AISI 316 L steel at the screw neck especially when movements occur (Steinemann). This applies for example to the tibia where considerable amounts of stress are transmitted from the screw to the plate under weight bearing conditions

Fig 1a—c The new screw hole which permits compression of the osteotomy (or fracture) when the screw is driven home offers adequate stability and prevents any locking effect

Fig 1a shows how a ball (screw) is guided in a sloped cylinder (screw hole). Any movement downward will result in a horizontal displacement. No sideways movement is possible. The position aimed at is the intersection of the two cylinders. This position offers the best stability without any locking effect. In the horizontal cylinder displacement towards the osteotomy is possible.

Fig 1b Projection of the cylinders into the screw hole and the ball shaped screw

Fig 1c Actual shape of the hole with the slot necessary for the screw neck and thread

It seemed desirable therefore to design a plate providing the same stability across an osteotomy or fracture as the rigid compression plate but avoiding the disadvantages listed above. Three alterations seemed essential:

- a) the original conical screw hole (see p. 8) was altered to a shape which is part of the geometrical figure formed by two cylinders intersecting at an obtuse angle (Fig. 1) a sloped one and one in the long axis of the plate (Figs. 1a and b). The screw entering this hole will first be guided by the sloping cylinder (Fig. 1c). A movement of the underlying bone towards the other fragment will result (Figs. 2A—D). The effect will be first to close and then to compress the fracture (see also page 48). This eliminates the need for an external compressor with the consequent need for additional surgical exposure in many cases (e.g. in undisplaced fractures). This design does not prevent the use of an external compressor if such a procedure should be desirable (e.g. in hip surgery).
- The horizontal cylinder will furthermore allow the screw to move a little further towards the fracture. This is to prevent any tendency to obstruct

MATERIAL AND METHOD

The gauge plate used in these experiments was similar to the one used above (see page 9) except for the following modifications

- 1) the metal used for the plates was commercially pure titanium of which the ultimate tensile strength is about 80 kp/mm and the Young's modulus is 11 000 Kp/mm. The dimensions of the plate were adjusted to compensate for the somewhat smaller ultimate tensile strength of the material
- 2) the load cell was similar with respect to mechanical and electrical construction and the plate was designed to prevent any deformation of the load cell due to bending forces. The gauge compartment was arranged to leave a gap of 1 mm between the bone and the bottom surface of the compartment thus allowing tissue to grow between the bone and the plate (Fig. 4)
- 3) the plate has 4—6 sloping cylindrical holes so that when the screws are driven home they exert a compression force on the bone in an axial direction (Figs. 1—2). The angle of slope was chosen to eliminate any loosening of the screw due to mechanical reasons. The screw is spherically countersunk exactly fitting the screw hole. Thus the screws have at least a semicircular line of contact with the screw in any position (Figs. 3 II & III). At the end of the slope when the screw has been fully driven home an area of contact between the screw and the hole is present amounting to part of the sphere (Fig. 3D). This position which offers maximum long term stability should be achieved whenever placing a screw. To permit simultaneous adaption and compression of an osteotomy or fracture the sloping cylinder provides a maximum horizontal displacement of 1.5 mm (Figs. 2A—D). The horizontal cylinder of the screw hole permits an additional horizontal movement of the order of 2.0 mm (Figs. 2D and F).

To position the screw in the hole of the DCP (dynamic compression plate) two different drill guides are used. The load guide (Fig. 5) places the screw in the slope as seen in figure 3 B. When driven home the head slides down the slope displacing the underlying bone towards the osteotomy. When the fracture or osteotomy gap has been closed and only slight further compression is needed the neutral guide is used to place the screw near its final position on the slope (Fig. 3 C). When the screw is driven home from this position it exerts additional mild compression. In practice the neutral guide will be used to position most of the screws and it is vital that on each side of an osteotomy or fracture at least 2 screws are fully driven home.

The experimental animals used were sheep from 2—4 years of age. Anaesthesia and surgery followed the procedure described above (p. 20) with these exceptions

To obtain well standardised experimental conditions for the fixation of the osteotomy a special drill guide was used to drill 2 holes on each side of the osteotomy. The drill guide was U shaped and when fixed to the bone prevented splitting during osteotomy. As above 2 plates were used to obtain enough stability for safe weight bearing. First the four hole plate was applied on the posterior aspect and then a six hole plate was fixed on the medial aspect of the tibia in a similar manner this latter plate giving about 20% higher compression

Fig 3 B—D Relation of screw head and screw hole and positioning of drill guides
 B Positioning of the screw by the load guide (dislocates the bone fragment approximately 1 mm when the screw is driven home)
 C Positioning of the screw by the neutral guide. Screw is placed near the end of the slope so that very little dislocational force results. Compression instituted by the load guide is slightly increased.

MATERIAL AND METHOD

The gauge plate used in these experiments was similar to the one used above (see page 9) except for the following modifications

- 1) the metal used for the plates was commercially pure titanium of which the ultimate tensile strength is about 80 Kp/mm and the Young's modulus is 11 000 Kp/mm. The dimensions of the plate were adjusted to compensate for the somewhat smaller ultimate tensile strength of the material
- 2) the load cell was similar with respect to mechanical and electrical construction and the plate was designed to prevent any deformation of the load cell due to bending forces. The gauge compartment was arranged to leave a gap of 1 mm between the bone and the bottom surface of the compartment thus allowing tissue to grow between the bone and the plate (Fig. 4)
- 3) the plate has 4—6 sloping cylindrical holes so that when the screws are driven home they exert a compression force on the bone in an axial direction (Figs. 1—2). The angle of slope was chosen to eliminate any loosening of the screw due to mechanical reasons. The screw is spherically countersunk exactly fitting the screw hole. Thus the screws have at least a semicircular line of contact with the screw in any position (Figs. 3 II & III). At the end of the slope when the screw has been fully driven home an area of contact between the screw and the hole is present amounting to part of the sphere (Fig. 3D). This position which offers maximum long term stability should be achieved whenever placing a screw. To permit simultaneous adaption and compression of an osteotomy or fracture the sloping cylinder provides a maximum horizontal displacement of 1.5 mm (Figs. 2A—D). The horizontal cylinder of the screw hole permits an additional horizontal movement of the order of 2.0 mm (Figs. 2D and E).

To position the screw in the hole of the DCP (dynamic compression plate) two different drill guides are used. The load guide (Fig. 5) places the screw in the slope as seen in figure 3B. When driven home the head slides down the slope displacing the underlying bone towards the osteotomy. When the fracture or osteotomy gap has been closed and only slight further compression is needed the neutral guide is used to place the screw near its final position on the slope (Fig. 3C). When the screw is driven home from this position it exerts additional mild compression. In practice the neutral guide will be used to position most of the screws and it is vital that on each side of an osteotomy or fracture at least 2 screws are fully driven home.

The experimental animals used were sheep from 2—4 years of age. Anaesthesia and surgery followed the procedure described above (p. 20) with these exceptions.

To obtain well standardised experimental conditions for the fixation of the osteotomy a special drill guide was used to drill 2 holes on each side of the osteotomy. The drill guide was U shaped and when fixed to the bone prevented splitting during osteotomy. As above 2 plates were used to obtain enough stability for safe weight bearing. First the four hole plate was applied on the posterior aspect and then a six hole plate was fixed on the medial aspect of the tibia in a similar manner this latter plate giving about 20% higher compression.

Fig 4 Gauge plate used to control stability of fixation achieved by the dynamic compression plate. The slightest movement of the fragments due to instability results in a sudden pressure change. No such changes were recorded with the dynamic compression plate when used correctly.

Fig 5 Gauge plate and drill guide. Two types of drill guides permit the achievement of compression at two different levels. The load guide with an eccentrically placed hole is used as shown in Fig 3 IV B. Driving home the screw then results in high compression. The neutral guide with the hole in the middle is used to achieve mild compression Fig 3 IV C. This guide should be generally used under the condition that good adaption is obtained before.

sion than the four hole plate To delay weight bearing until 3 weeks a simple tenotomy of the Achilles tendon was performed

The plates used in animal experiments to be reported here were DCP's provided with strain gauges in a similar manner as outlined for the AO* compression plate (see p 9) The DCP gauge plate is shown in figures 4 and 5 An additional simple metal clamp was employed near the plate to prevent the leads from breaking Thus at the end of the experiment a final reading could be taken even after a lead break by exposing the wire where it had been protected by the clamp In this way a recalibration also could be made after removal of the plate

The above mentioned experiment was performed on 8 sheep An additional group of experiments was done with 4 sheep In this group the osteotomies were performed on the metatarsus using a single plate for fixation and weight bearing was prevented by combining ankle arthrodesis with tenotomy 3 weeks before the osteotomy These animals were observed for 16 weeks An additional animal with a tibia osteotomy fixed by two DCP gauge plates was observed during 16 weeks In this animal weight bearing was not delayed by tenotomy The specimens of bone were sectioned as described above (see p 20)

RESULTS

The pressure recordings of 8 consecutive experiments which lasted two months are shown in figure 6 The pressure initially applied ranged from 70-180 Kp As with the conventional steel plate the pressure decreased progressively after an initial somewhat steeper drop In those animals which were observed during 4 months pressure gradually decreased before it approached zero with no sudden drop at any point

Fig 6 Recordings of interfragmentary pressure in a group of transverse tibia osteotomies fixed by dynamic compression plates There is no sudden fall of pressure

* or ASIF

Fig 4 Gauge plate used to control stability of fixation achieved by the dynamic compression plate. The slightest movement of the fragments due to instability results in a sudden pressure change. No such changes were recorded with the dynamic compression plate when used correctly.

Fig 5 Gauge plate and drill guide. Two types of drill guides permit the achievement of compression at two different levels. The load guide with an eccentrically placed hole is used as shown in Fig 3 IV B. Driving home the screw then results in high compression. The neutral guide with the hole in the middle is used to achieve mild compression. Fig 3 IV C. This guide should be generally used under the condition that good adaption is obtained before.

screw seat did not offer optimum lateral stability. This latter problem has plagued most other slotted plates. The key to success is congruity between screw and plate which in the present plate is produced by three dimensional seating of a spherically countersunk screw head in a cylindrically countersunk plate. This design overcomes the chief disadvantage of the ordinary slotted plates while keeping its primary asset of preventing the plate from holding the fracture gap open.

Measurements with DCP's (dynamic compression plates) provided with strain gauges (DCP gauge plates) showed that with the DCP axial compression of the same order as with AO^{*} compression plates with external compressor was obtained. Before use in humans it was advantageous to determine whether the DCP could be relied upon to maintain rigidity as long as the original AO compression plate. It was demonstrated that with two DCP gauge plates applied to an osteotomised sheep tibia the rate of decrease of compression measured over 8 weeks matched that obtained with the AO plate (p. 21). Experiments with osteotomised metatarsi of sheep stabilised by DCP gauge plates showed a slow decay of pressure over 8 weeks with demonstrable compression forces up to 4 months. At no time did a sudden drop of pressure indicate the presence of instability.

The histological findings of Haversian remodelling directly bridging the osteotomy without formation of external callus were identical to those observed with conventional steel plates. At 8 weeks the osteotomy was bridged by some osteons but remodelling of the cortex was only partial (Fig. 8). At 16 weeks examination of the metatarsi and of the tibia showed the osteotomy to be clinically united with minimal callus formation (Fig. 9). The cortex was undergoing extensive Haversian remodelling with much osteogenesis within the canals. The DCP clearly fulfil the function of giving sufficient rigidity to allow primary healing.

The main function of the horizontal cylinder is to allow for minor displacements of the screws relative to the long axis of the plate. The present design of the screw hole permits a screw which has been positioned at the intersection of the two cylinders to move only towards the fracture gap. The major reason for allowing this kind of displacement is to prevent screws from locking during the procedure of closing the fracture gap (this procedure may involve several adjustments of the screws in order to ensure optimum fixation). An additional advantage of the allowed axial displacement is to prevent an eventual imperfect closure from being held apart. This type of design also results in a more beneficial stress distribution. In previous experiments with AO gauge plates we have observed changes of the initially applied pressure when seating subsequent screws. In practice the DCP served the above mentioned function while maintaining a satisfactory amount of compression and stability.

The screw has a spherical seat. This shape of the screw countersink allows flexibility in directing the line of action of the screws to achieve the desired force on the fracture surfaces. It also permits to obtain a better grip in comminute fractures.

Corrosion and fatigue fractures in compression plates usually occurred in the outer screw holes or at some other highly stressed point of a plate applied to a

* or ASIF

Fig 7 Close up view of a metatarsus 16 weeks after transverse osteotomy and internal fixation with DCP gauge plate. The osteotomy is scarcely visible. There is minimal callus formation and no periosteal reaction can be detected.

Radiographic and macroscopic examinations both showed the absence of external callus formation (Fig 7). The titanium plate provoked no visible reaction in the tissue and in every case a thin sheet of vascular tissue was found to be lying in contact with the metal. The bone adjacent to the plate was well vascularised. No titanium dissolution products were observed in the tissue although metal deposits sometimes are seen in human cases.

Histology revealed that the osteotomy was directly bridged by new osteons in the pressure area (Fig 9). Beside this area of contact and pressure near the plates there was usually a gap between the fragments on the opposite side of the osteotomy. Where there was a gap the osteotomised bone clearly did not support any pressure. Nevertheless such a gap area benefitted from the stability provided by the area which was in contact and supported pressure. Under such stable conditions small gaps were directly bridged by new osteons (Fig 8) while larger gaps were first filled with lamellar bone and then remodelled in the long axis of bone (see p 23 Fig 6).

At 8 weeks remodelling was still incomplete (Fig 8). At 16 weeks the osteotomy was healed (Fig 9). There was no significant resorption of the osteotomy surface seen either at the pressure side or at the gap side and in no case was any cartilage or fibrous tissue detected in the gap. As seen in figure 9 there was minimal callus present in spite of early full weight bearing in the tibia osteotomy which was observed for 16 weeks.

DISCUSSION

As Egger claimed the function of an implant in internal fixation is to counteract the forces producing shear or distraction. His plate was considered to have failed to achieve this result however since it did not apply compression to counter distraction and did not fully prevent shear since the shape of its

* distraction is a movement which results in opening the fracture gap

screw seat did not offer optimum lateral stability. This latter problem has plagued most other slotted plates. The key to success is congruity between screw and plate which in the present plate is produced by three dimensional seating of a spherically countersunk screw head in a cylindrically countersunk plate. This design overcomes the chief disadvantage of the ordinary slotted plates while keeping its primary asset of preventing the plate from holding the fracture gap open.

Measurements with DCP's (dynamic compression plates) provided with strain gauges (DCP gauge plates) showed that with the DCP axial compression of the same order as with AO compression plates with external compressor was obtained. Before use in humans it was advantageous to determine whether the DCP could be relied upon to maintain rigidity as long as the original AO* compression plate. It was demonstrated that with two DCP gauge plates applied to an osteotomised sheep tibia the rate of decrease of compression measured over 8 weeks matched that obtained with the AO plate (p 71). Experiments with osteotomised metatarsi of sheep stabilised by DCP gauge plates showed a slow decay of pressure over 8 weeks with demonstrable compression forces up to 4 months. At no time did a sudden drop of pressure indicate the presence of instability.

The histological findings of Haversian remodelling directly bridging the osteotomy without formation of external callus were identical to those observed with conventional steel plates. At 8 weeks the osteotomy was bridged by some osteons but remodelling of the cortex was only partial (Fig. 8). At 16 weeks examination of the metatarsi and of the tibia showed the osteotomy to be clinically united with minimal callus formation (Fig. 9). The cortex was undergoing extensive Haversian remodelling with much osteogenesis within the canals. The DCP clearly fulfils the function of giving sufficient rigidity to allow primary healing.

The main function of the horizontal cylinder is to allow for minor displacements of the screws relative to the long axis of the plate. The present design of the screw hole permits a screw which has been positioned at the intersection of the two cylinders to move only towards the fracture gap. The major reason for allowing this kind of displacement is to prevent screws from locking during the procedure of closing the fracture gap (this procedure may involve several adjustments of the screws in order to ensure optimum fixation). An additional advantage of the allowed axial displacement is to prevent an eventual imperfect closure from being held apart. This type of design also results in a more beneficial stress distribution. In previous experiments with AO* gauge plates we have observed changes of the initially applied pressure when seating subsequent screws. In practice the DCP served the above mentioned function while maintaining a satisfactory amount of compression and stability.

The screw has a spherical seat. This shape of the screw countersink allows flexibility in directing the line of action of the screws to achieve the desired force on the fracture surfaces. It also permits to obtain a better grip in comminute fractures.

Corrosion and fatigue fractures in compression plates usually occurred in the inter screw holes or at some other highly stressed point of a plate applied to a

* or ASIF

Fig 7 Close up view of a metatarsus 16 weeks after transverse osteotomy and internal fixation with DCP gauge plate The osteotomy is scarcely visible There is minimal callus formation and no periosteal reaction can be detected

Radiographic and macroscopic examinations both showed the absence of external callus formation (Fig 7) The titanium plate provoked no visible reaction in the tissue and in every case a thin sheet of vascular tissue was found to be lying in contact with the metal The bone adjacent to the plate was well vascularised No titanium dissolution products were observed in the tissue although metal deposits sometimes are seen in human cases

Histology revealed that the osteotomy was directly bridged by new osteons in the pressure area (Fig 9) Beside this area of contact and pressure near the plates there was usually a gap between the fragments on the opposite side of the osteotomy Where there was a gap the osteotomised bone clearly did not support any pressure Nevertheless such a gap area benefitted from the stability provided by the area which was in contact and supported pressure Under such stable conditions small gaps were directly bridged by new osteons (Fig 8) while larger gaps were first filled with lamellar bone and then remodelled in the long axis of bone (see p 23 Fig 6)

At 8 weeks remodelling was still incomplete (Fig 8) at 16 weeks the osteotomy was healed (Fig 9) There was no significant resorption of the osteotomy surface seen either at the «pressure side» or at the «gap side» and in no case was any cartilage or fibrous tissue detected in the gap As seen in figure 9 there was minimal callus present in spite of early full weight bearing in the tibia osteotomy which was observed for 16 weeks

DISCUSSION

As Egger claimed the function of an implant in internal fixation is to counteract the forces producing shear or distraction* His plate was considered to have failed to achieve this result however since it did not apply compression to counter distraction and did not fully prevent shear since the shape of its

* distraction is a movement which results in opening the fracture gap

weight bearing bone (e.g. the tibia). Such stress concentrations may also be created by eccentric positioning of a screw in a conical seat. The present plate and screw design prevents these stress concentrations. In our series of experiments with sheep good rigidity was maintained and prompt healing achieved in two types of experimental osteotomies. Based on these results a clinical testing program has been initiated. Preliminary results are reported in a separate paper (Allgower et al. see p. 45).

SUMMARY

Rigid fixation by conventional compression techniques while permitting economical primary bone healing is liable to protect bone from physiological stresses and may thus induce osteoporosis of the cortex. Furthermore there is a locking action of a screw hole with conical fitting under weight bearing conditions.

A compression plate was constructed therefore which would provide the same amount of stability but prevent locking action of the screws and permit axial compression without the use of an external compressor.

Long term pressure recording as well as histology give evidence of maintained stability.

CLINICAL EXPERIENCE WITH A NEW COMPRESSION PLATE «DCP»

INTRODUCTION

Three groups of experimental findings are relevant to the clinical application of compression plates and to possible improvements in their design

Static loads of the order of 60 to 140 Kp applied to cortical bone are found to be maintained over several months and during this time gradually diminish to near zero pressure. There is no sudden loss of pressure due to bone necrosis. From an engineering standpoint such a compression system therefore is able to secure maximum stability of internal fixation. Biologically it is compatible with the healing process. The gradual pressure loss mentioned above is induced by bone remodelling of the Haversian system slowly replacing the compressed osteons by new ones. There is no appreciable difference in remodelling of a cortex whether an osteotomy is present or not provided the contact surface is rigidly stabilized. Remodelling however leads to bridging of the osteotomy gap resulting in direct repair (Perren et al see p 23)

Such a process has been found in the osteotomised radius in the dog (Schenk et al) in the tibia of the sheep (Perren et al see p 24) and in the tibia of the rabbit (Rahn et al). It has also been observed in the tibia of a human adult who died three months after internal fixation.

Endosteal or periosteal contribution to bone remodelling consists mainly of increased blood supply to the cortex. To what extent endosteal or periosteal callus formation occurs depends on the stability of the internal fixation (Hutzschenreuter et al). The rationale of the rigid AO* compression system therefore is well documented and the high success rate after adequate operation is not surprising (Anderson Rhinelander M. E. Müller Allgöwer & Willenegger).

The rigid connection between screws anchored in the comparatively deformable bone on the one side and in the rigid plate on the other has however certain drawbacks

- under weight bearing conditions a rigidly plated bone undergoes a smaller elastic deformation than a bone without plate. This difference is the greater the longer the plate. A screw head at the end of a 15 cm plate will have a tendency to move towards the center of the plate over a distance of about 30μ when weight bearing with 100 Kp is instituted. This gives rise to considerable stress at the point of contact between screw and plate and may induce corrosion and even fatigue fracture of the screw.
- in the conventional procedure using the separate compressor compression is instituted at the beginning of the procedure and then the screws are inserted into the plate. Eccentricity in positioning of conically seated screws in such a plate will result in unpredictable alterations in the applied load and in stress concentrations.
- elastic deformation of the cortex will be reduced by the locking effect of the tightly fitting screws because the complex of bone and plate will become very rigid. The rigidly fixed plate with its high Young's modulus results in considerable stress protection to the plated part of the diaphysis.

* or ASIF

especially when double plates are used. This — according to Wolff's law of adaptation to functional demand — will cause bone destruction to prevail over osteogenesis in the course of remodelling and thus lead to osteoporosis of the cortex. In turn this may give rise to fatigue fracture after removal of the implant.

The locking effect of the screws as well as part of the stress protection can be eliminated by a slotted configuration of the screw holes and an increase in deformability of the plate provided that the relative shape of the screw seat is able to protect the fracture from shear and distraction. Together with Perren and Russenberger we have been able to design a screw seat which enables a tension force to be applied to the plate by the screw head when the screw is driven home (Perren et al. see p. 32). The Dynamic Compression Plate (DCP) has been described previously. The DCP has been proved to offer adequate stability of fixation. Its main specification will be given under material and method. It is the purpose of this paper to report our observations in a consecutive series of clinical cases using the DCP. Apart from eliminating in most of our cases the necessity for any compression device (thus allowing a shorter incision) this plate seems to offer definite biomechanical as well as metallurgical advantages over the conventional plates made of AISI 316 L as described previously (M. E. Müller, Allgöwer & Willenegger).

MATERIAL AND METHOD

The dynamic compression plate is made of commercially pure titanium treated to increase the ultimate tensile strength. The Young's modulus of titanium (11000 kp/mm²) is markedly lower than that of stainless steel or of vitallium®. The fatigue resistance of titanium is good (Steinemann) and its resistance to corrosion in body fluid is excellent (Hoar & Mears, Steinemann) as in this fluid titanium does not show any pitting corrosion.

The overall shape of the plate as seen in figure 1 corresponds to that of the AO* plate. The cross section of the dynamic compression plate is slightly larger than of the AO* plate. This is to allow for the somewhat smaller ultimate tensile strength of titanium (80 kp/mm²) when compared to AO* steel (90 kp/mm²).

The screw seat has been designed as illustrated in figures 2 and 3 in order to combine

- compression of the fracture when the screw is driven home
- firm precision fit of the screw head in the screw hole at all times
- prevention of locking effect of the screw

The screw hole, the shape of which has been described in detail (Perren et al. see p. 32) is part of the geometrical figure formed by two cylinders, a sloping one and a horizontal one intersecting at an obtuse angle. The screw has a spherically countersunk head exactly fitting the cylinders of the screw hole. The line of contact between screw and screw hole is a semicircular line. At the intersection of the two hemi-cylinders the contact area is part of a sphere. In all other aspects the screw is identical with the AO* screw. It is not self-tapping and has a hexagonalimbus. The screw holes of the plate ends will also accommodate cancellous screws with a larger thread.

Fig. 1 Large and small dynamic compression plate. DCP with cortical and cancellous screws (photograph and section) made of commercially pure titanium. Apart from the configuration of the screw holes and screw heads the plates are similar to the conventional plates made of AISI 316 L steel described by M. E. Muller, Allgower and Willenegger.

To position the screw in the screw hole drill guides are used (Fig. 4). Two different types of drill guide (Fig. 5) place the screw either in the middle of the sloping cylinder (load guide A) or near its lower end (neutral guide B). The use of the load guide produces a horizontal displacement of the fragments toward the fracture of about 1 mm when the screw is driven home. This guide is used to eliminate the fracture gap. The neutral guide is used when the fracture gap has been closed and put under pressure so that only slight further compression is needed.

When the screw is driven home there remains the possibility of a passive movement of about 2 mm of the screw head towards the end of the horizontal hemicylindrical screw hole. This should prevent any locking effect of the screw to avoid unpredictable loss of load when additional screws are inserted and to reduce the load of each screw. Thus axial stress will be transmitted to the cortex when weight bearing is begun or muscular forces begin to act on bones such as those of the upper limb.

Up to now 300 human cases have been operated using the DCP with very gratifying results. In this first report we only include the first 60 consecutive cases done between January 1966 and February 1967 which until now have been fully followed up, namely:

- tibia 53 fresh fractures (two cases of non union and one refracture)
- radius 2 shaft fractures
- femur 4 fresh fractures one infected non union
- clavicle 1 non union

Three patients died from coronary occlusion or pulmonary embolism in the weeks following their injury and therefore are not included in this report although bone healing proceeded normally.

There remained 50 tibial fractures in 49 patients who could all be followed up fully. They constitute the main part of this report. They were contacted 6–8 months after operation by a questionnaire and one year after operation there was an individual examination of each patient. After a mean time of 69 weeks (from 45 to 100 weeks) all implants were removed according to the following procedure:

- 1 Distal part of scar opened so that the distal three screws could be exposed
- 2 Removal of overlying tissue for histological examination
- 3 Color photograph of plate in situ
- 4 Removal of all other screws by small incisions and removal of the plate
- 5 Photograph of plate bed
- 6 Biopsy of plate bed for metallurgical and histological examination

Fig 2a

Fig 2b

Fig 2c
 Fig 2 Compression fixation by the DCP. Compression is obtained by the spherical gliding principle. The spherically countersunk screw head is congruent to the hemicylindrical sloped screw hole and approximates the bone ends when driven home. At the end of the slope the hemispherical screw head has a larger contact area with the plate corresponding to part of a sphere (see also Perren et al. Fig. 1 p. 32). The screw head in figure 2c lies at the beginning of the horizontal hemicylinder of the screw hole which offers the possibility of a passive movement of the screw.

To position the screw in the screw hole drill guides are used (Fig. 4). Two different types of drill guide (Fig. 5) place the screw either in the middle of the sloping cylinder (load guide A) or near its lower end (neutral guide B). The use of the load guide produces a horizontal displacement of the fragments toward the fracture of about 1 mm when the screw is driven home. This guide is used to eliminate the fracture gap. The neutral guide is used when the fracture gap has been closed and put under pressure so that only slight further compression is needed.

When the screw is driven home there remains the possibility of a passive movement of about 2 mm of the screw head towards the end of the horizontal hemicylindrical screw hole. This should prevent any locking effect of the screw to avoid unpredictable loss of load when additional screws are inserted and to reduce the load of each screw. Thus axial stress will be transmitted to the cortex when weight bearing is begun or muscular forces begin to act on bones such as those of the upper limb.

Up to now 300 human cases have been operated using the DCP with very gratifying results. In this first report we only include the first 60 consecutive cases done between January 1966 and February 1967 which until now have been fully followed up, namely:

RESULTS

Tibial fractures (50 fractures in 49 patients)

The average hospital stay was 11 days. No infection occurred. Two patients showed local tenderness on premature weight bearing which immediately subsided when weight bearing was discontinued. No secondary operation was required except for the removal of the plate.

During the course of healing there was little discomfort in the operated leg except for the cases mentioned above. On removal of the metal 65% considered themselves completely normal. 35% had minor complaints. Ankle and subtalar joints recovered completely.

All 50 fractures showed good radiological consolidation at the time of removal of the metal (Figs 6c and d). The cortical bone appeared quite homogeneous and dense even deep to the plate. There seemed to be more evidence of endosteal callus formation than in cases plated with conventional AO* plates but the difference seems hardly significant. The rate of so called primary bone healing which means healing with no radiological evidence of callus was 50% in this series compared to 70% in previous series with conventional AO* plates.

In 37 fractures we were able to remove all implants ourselves. In each case the tissue immediately deep to the plate was macroscopically well vascularized. The other tissues surrounding the plate showed in most cases a firm contact with the implant so when removing the plate a thin layer of vascularized tissue adhered to the titanium implant. Of 37 fractures 18 showed no evidence of metal deposits whatsoever while 17 had a slight coloration of the tissue surrounding the distal part of the plate located especially at the neck of the screws. According to Steinemann such a coloration corresponds to about 100 PPM of titanium in the tissue. Two cases showed significant metallic coloration of the tissue. It was interesting that visible metal deposits were not paralleled by clinical signs of irritation.

Histological examination of the tissue surrounding the plate revealed a comparatively small layer of fibrous tissue adjacent to plate (Fig 7a). Capillaries were seen in the immediate neighbourhood of the implant (Fig 7b). According to the macroscopic findings in about half of the cases metal deposits were seen the quantity of which ranged from detectable to significant deposition (Fig 7c). Histologically titanium deposits hardly provoked any inflammatory reaction or proliferation. This finding is consistent with other experimental findings (Steinemann et al).

Of special interest was the fact that the slotted holes of these DCPs were filled with bone. The removal of the plate may thus be somewhat more difficult than with ordinary stainless steel plates. Such a bone formation certainly indicates the good tolerance of the metal employed.

Forearm fractures and non unions

Both our radii united without any immobilisation of the injured forearm and without any discomfort to the patient (Figs 9 and 10). Figure 11 shows a recent

V Dislocational effects of the screw when driven home

case not included in the above mentioned series of a non union of the forearm healing rapidly after fixation by DCP's

The rather avascular non union of the clavicle (Fig 8a) was treated by compression fixation alone without any cancellous bone graft. At 50 weeks it showed good consolidation (Fig 8b) permitting removal of the metal at this time

The infected non union of the femur constituted a major challenge because of extensive cortical necrosis and bone defect which had to be replaced by cancellous bone grafts. For stabilization a double plate was required and despite the rather massive implant bony union was surprisingly rapid and wound discharge was soon minimal. It subsided 6 months before removal of the plates. This is a most unusual observation when using other material in infected sites. Bone healing in the face of infection may occur with various metallic plates but usually drainage continues as long as the implant is in place. In a subsequent series not reported here we had a similar experience with other infected non unions of the femur where the wound also healed promptly

DISCUSSION

The rigid AO* compression plate of stainless steel facilitates the main aims in the operative treatment of fractures and non unions namely full functional recovery combining four principles

- anatomical reduction
- atraumatic technique
- stable fixation
- immediate postoperative mobilisation without external fixation

The stability achieved is sufficient to neutralize the fracture or the non union allowing cortical bone healing together with immediate postoperative mobilization of the injured limb. The drawbacks of the system are marked stress protection of the plated cortex by the locking action of the tightly fitting screws and unpredictable changes of compression by screws inserted eccentrically

The question arises whether it is possible to avoid the disadvantages of the rigid compression plate without losing its advantages namely the successful neutralization and compression of the fracture

In osteotomized tibiae of the sheep fixed with DCPs we have indeed been able to show that the rate of pressure fall is identical to that observed with conventional AO* plates (Perren et al see p 21). This is good evidence that stability is in fact well maintained. Results in the clinical series confirm this point very well. Not one failure due to instability was encountered in the 60 cases.

The next question is whether we have really eliminated the above mentioned drawbacks of the rigid compression plates. There are some indications that this is indeed true. Cortical bone in the plated area seems more solid and more homogenous radiologically when using DCP than with ordinary AO* plates. On removal of the plate the site appears to be distinctly better vascularized. The patients also complain less of discomfort in the lower leg fractures but this point evidently is very difficult to quantitate

Fig 9b Result after 62 weeks

Fig 10a Transverse radius fracture fixed by a six hole DCP and treated without any external fixation showing full functional recovery one month after operation

Fig 10b Result after 70 weeks

Since we are introducing two changes simultaneously — configuration of the screw hole and change of metal — we are not quite sure which has played the greater role in this respect. Titanium however seems to be surprisingly well tolerated and the increased deformability of the DCP certainly did not compromise the results.

Figs 11 a c a) Non union after inadequate fixation of a forearm fracture
b) X rays taken after 1 1/2 months
c) X rays taken after 8 months showing bony union almost completed

Pitting corrosion is no problem with titanium. The metal deposits present in about half the cases of this series stemmed probably from pickling. The had apparently little clinical significance and did not induce tissue reaction (Figs 7a-c). Using anodically oxidized titanium plates we have not observed metal deposits in a further clinical series of 300 cases not reported here.

It is well known that Eggers as well as Bagby advocated the use of slotted plates. An internal fixation achieved by the use of the Eggers plate does not resist distraction nor shear. The lateral support of Bagby's plate was not considered to be optimal. From our previous observations in the experimental animals and now in clinical cases we may conclude that it is possible to use self-compressing plates if care is taken that lateral stability and axial compression are as well maintained as with a conventional compression plate. This plate (DCP) combining the practical benefit of requiring less exposure with a more physiological stress transmission to the bone cortex therefore may offer some distinct advantages.

SUMMARY

The dynamic compression plate (DCP) has been successfully applied in fresh fractures as well as in infected and non infected non unions. Detailed instructions for its application are given. The DCP is well tolerated by the tissue and offers advantage of less exposure and more adaptability to the individual case. The experimental prove of continuous stability as reported in an earlier paper is born out by clinical experience.

ACKNOWLEDGEMENTS

I wish to express my warmest gratitude towards Professor Carl Hirsch Docent Ingemar Petersen and Professor Robert Magnusson, who introduced me into the different types of research technique used in this work and have given constructive criticism encouraging help and stimulation in all respects

Mr Roland Kadefors M E E and Mr Lars Lindstrom M E E at the Division of Applied Electronics Chalmers University of Technology I thank for valuable assistance calculations and appreciated discussions

I am indebted to Mr Ingvar Holmberg Ph D the Department of Statistics University of Goteborg for his help with the statistical analyses I also owe many thanks to the staff of the Clinical Neurophysiological Laboratory where most of the work was carried out Furthermore I am grateful to Miss Gerd Grunden and Miss Gunilla Blidberg for secretarial work

The investigations were supported by grants from the Faculty of Medicine of the University of Goteborg and The Medical Society of Goteborg

INTRODUCTION

As a result of the great number of traumatic injuries to the extremities during World War II there was a renewed interest in various types of prostheses. During latter decades great importance has been attributed to the rehabilitation of patients with impaired motor function by means of orthoses. Prostheses and also orthoses were previously designed so that the force required by the device had to be mobilized by the patient. The standard method of controlling the conventional prostheses and orthoses in the upper extremities is a mechanical control by gross body movements of the trunk and the extremities transmitted by means of cables attached to the harness. This type of mechanical control is disadvantageous mainly because the force of the movements in the prosthesis will be limited, the range of motion will be small and at the same time the necessary movements will cause the patient discomfort and fatigue. Furthermore the functions of the prosthesis are limited as several movements cannot be performed simultaneously without important parts of the body being bound to the control function in a very disturbing way.

Advanced technical research has permitted the design of new types of prostheses and orthoses which are supplied with an external source of power. Already in 1919 a method of converting electric power into mechanical movements in prostheses was published (*Borchardt & Schlesinger 1919*). During the interwar period this type of prosthesis and similar designs were unpractical because of their weight and the difficulties for the patients to control them adequately. Two different sources were later utilized to deliver power to the prostheses and the orthoses, namely pneumatic and electric power. For pneumatic power liquid carbon dioxide was used for instance in 'The Heidelberg pneumatic arm prosthesis' (*Heil 1977*) and 'The Hendon pneumatic prosthesis motor' (*Kinnier Wilson 1960*). The great advantages of pneumatic prostheses as compared to electric were their smooth, comparatively noiseless running and their light weight.

During World War II and the following wars there was a renewed interest in prostheses equipped with external power. Towards the end of World War II Walter in Berlin began designing an electric hand prosthesis which later has developed into the so-called French electric hand (*Lucaccini, Kaiser &*

Lyman 1966) Research of many years duration began in the USA in 1946 to design an electric arm prosthesis which finally resulted in five different types (Alderson 1954) A common phenomenon in these American models was that only a few control movements were required of the amputee to release multiple sequentially coded movements in the prosthesis This proved to be unnatural for the patient and a considerable amount of practice was required before the amputees could use these prostheses Thus they were not generally accepted The great problem has been to enable the patients to control prostheses and orthoses which are operated by external power The difficulties become even greater with complicated devices having more degrees of freedom For each direction of motion the action as a rule demands one control site i.e. a part of the body from which control impulses can be picked up

The control of the first electric prostheses introduced after World War II was carried out mechanically by wires or by utilizing the change in volume to which a muscle is subjected when contracted Mechanical transducers were fitted in the socket of the prosthesis causing an impulse when the amputee contracted his stump muscles Berger & Huppert (1952) first suggested that in order to obtain a better control of the externally powered prostheses the electric signals generated in connection with muscular contraction should be used as a control signal Originally this possibility was mentioned by Wiener (1947) who pointed out that myoelectric signals could be detected in the stump muscles of arm amputees and that these signals would probably allow control of a prosthesis (Bottomley 1965) The release of myoelectric signals—in voluntary contraction—is via central and peripheral neurons controlled by the brain Advantage is taken of this fact when utilizing myoelectric signals for prosthesis control This type of control will thus be experienced by the amputee as more natural than the conventional mechanical control (McLaurin 1965) Furthermore no extensive and disturbing movements of the body are demanded less muscular force is required and the risk of the patient becoming fatigued is reduced A further important fact is that the patient will receive proprioceptive impulses from the muscles involved giving a sensation of communication with the prosthesis (Popov 1965 Scott 1966)

In arm amputees and patients with impaired motion due to pareses of different origin the myoelectric signals often differ in appearance The frequency and degree of these changes in various muscles of arm amputees are discussed in this paper Furthermore the ability of arm amputees and normals to utilize their myoelectric signals as control impulses and the electrode problems involved in picking up these signals have been studied

HISTORICAL REVIEW

Arm Amputees

Although the history of prostheses is closely connected with the years following the two great World Wars the number of amputations in civilians considerably exceed that in disabled soldiers. As a result of the War 1941-1945 the number of arm and leg amputations in the USA was estimated to be 40 000 while for civilians the corresponding number a few years ago was 500 000 (Alter 1966). In the same country the total number of recent amputations was approximately 35 000 per annum (Lussell 1961). The British Ministry of Health compiles all annual amputations also including frequency, age, sex and etiology. These reports are forwarded by the prostheses workshops. During a number of years this has enabled the relation between arm and leg amputees to be determined, the ratio being one to ten. At the same time an annually increased frequency of new amputations could be observed in Great Britain in agreement with a series of leg amputations in Sweden examined by Hansson (1964).

In 1962 Great Britain thus registered approximately 300 fresh arm amputations. Based on the frequency of fitted prostheses the rate of annual leg amputations in Sweden was recently estimated at 1000 cases (Herberts 1968). The number of new arm amputations in that type of study is more difficult to determine but the frequency of cases was assessed at 100 per annum which also resulted in a relation of one to ten between arm and leg amputees. The total number of arm amputees in Sweden was estimated at 900 patients by the Swedish Committee for Disabled in 1955 while the frequency at present could be estimated at 1500.

The difference in sex is obvious among arm amputees inasmuch as the males are in the majority. Thus Watkins & Ford (1962) in a follow up of 150 arm amputees found five times more males than females. The male predominance among arm amputees was also noted by Hansson (1966) who in a study on 243 arm prosthesis applications found nine males to one female.

Contrary to leg amputation the loss of an arm generally strikes younger people. Several series reveal that most of the patients are younger than 50 years of age at the time of accident, the mean age ranging from 20 to 30 years (Watkins & Ford 1962, Hansson 1966).

Lyman 1966) Research of many years duration began in the USA in 1946 to design an electric arm prosthesis which finally resulted in five different types (*Alderson, 1954*) A common phenomenon in these American models was that only a few control movements were required of the amputee to release multiple sequentially coded movements in the prosthesis This proved to be unnatural for the patient and a considerable amount of practice was required before the amputees could use these prostheses Thus they were not generally accepted The great problem has been to enable the patients to control prostheses and orthoses which are operated by external power The difficulties become even greater with complicated devices having more degrees of freedom For each direction of motion the action as a rule demands one control site i.e. a part of the body from which control impulses can be picked up

The control of the first electric prostheses introduced after World War II was carried out mechanically by wires or by utilizing the change in volume to which a muscle is subjected when contracted Mechanical transducers were fitted in the socket of the prosthesis causing an impulse when the amputee contracted his stump muscles *Berger & Huppert (1952)* first suggested that in order to obtain a better control of the externally powered prostheses the electric signals generated in connection with muscular contraction should be used as a control signal Originally this possibility was mentioned by *Wiener (1947)* who pointed out that myoelectric signals could be detected in the stump muscles of arm amputees and that these signals would probably allow control of a prosthesis (*Bottomley 1965*) The release of myoelectric signals—in voluntary contraction—is via central and peripheral neurons controlled by the brain Advantage is taken of this fact when utilizing myoelectric signals for prosthesis control This type of control will thus be experienced by the amputee as more natural than the conventional mechanical control (*McLaurin 1965*) Furthermore no extensive and disturbing movements of the body are demanded less muscular force is required and the risk of the patient becoming fatigued is reduced A further important fact is that the patient will receive proprioceptive impulses from the muscles involved giving a sensation of communication with the prosthesis (*Popov 1965 Scott 1966*)

In arm amputees and patients with impaired motion due to pareses of different origin the myoelectric signals often differ in appearance The frequency and degree of these changes in various muscles of arm amputees are discussed in this paper Furthermore the ability of arm amputees and normals to utilize their myoelectric signals as control impulses and the electrode problems involved in picking up these signals have been studied

performed on the indication of a tumour. As most of the arm amputations are the result of a trauma it is comprehensible that the remaining muscles, nerves and other tissues may reveal changes in an amputated extremity. These changes are not merely localized to the stump area; there may also be severe pathological changes proximally in the injured extremity due to traction of the nerves and vessels at the time of the accident.

Myoelectric Control Systems

It was three British scientists *Battye, Nightingale & Willis* (1955) who again suggested that myoelectric signals should be possible to utilize for control of prostheses and who introduced a by now classic description of a myoelectric control system. They proved that below elbow amputees could actively control prehension in a simple prosthesis by myoelectric signals produced in the stump muscles. Patients recently operated upon were considered to control the prosthesis with less difficulty than those earlier amputated. The new technique of the transistor made the work with electronic control systems more attractive than before. Disturbances in the myoelectric signals from the external surroundings, from the skin electrodes and from the amplifiers were pointed out. A few years later a myoelectrically controlled hand prosthesis was developed in the Soviet Union (*Kobrinshii et al.* 1960). In both the e prostheses systems skin electrodes were utilized to pick up the myoelectric signals. The Russians have applied their hand prosthesis in at least 1000 patients (*Lymark* 1964) and it has also been sold on a licence for clinical application to Great Britain (*McKenzie* 1966) and Canada (*Sherman* 1964; *Cingras et al.* 1966). This prosthesis lacks active pronation and supination and does not offer any proportional grip. It is easy to subscribe to the favourable points raised by *Scott* (1966) about the Russian electric hand having been released for clinical use and criticism which allowed valuable practical experience to be gained. *Cingras et al.* (1966) found the technical design incomplete and modified several components on the basis of their experience.

In the beginning of the 1960s a number of myoelectrically controlled hand prostheses were introduced (*Horn* 1963; *Bottomley & Coucell* 1964; *Hirsch, Kaur & Petersen* 1964; *Schmidt* 1964; *Anoules, Stevens & Howe* 1965). All these systems merely offered one function: prehension. Skin electrodes were used to pick up the myoelectric signals and the remaining extensor and flexor muscles of the forearm stump were utilized as control sites. The brachial biceps and triceps muscles and other groups of muscles have also been suggested. No proportional control of the grip could be offered with these prosthetic systems. A few attempts have been made to obtain control of more functions than pre-

Etiological studies of arm amputations show that most cases were caused by trauma. Thus in 60-64 per cent of the cases trauma was the cause of the patient's handicap. Following trauma congenital aplasia commonly resulted in amputation whereas malignant tumours amounted to less than 10 per cent as is shown in Table 1. The traumatic lesions were mostly due to industrial accidents. During 1962 in Great Britain traumatic arm amputations were reported to be caused by industrial accidents in 60 per cent whereas approximately 20 per cent were due to traffic accidents.

Table 1 Causes of amputation in two series

	No of cases	Trauma	Congenital defect	Tumour
Great Britain acc to Brit Ministr of Health 1962	296	60%	27%	6%
Gothenburg Sweden acc to Hansson 1966	74	72%	16%	8%

In principle arms can be amputated at six functionally different levels. The level of amputation is decisive for the degree of loss of function and the resulting handicap. In exarticulation of the wrist there generally remains a satisfactory pronation and supination ability but there is lack of prehension. In exarticulation of the shoulder of course no function whatever remains. The amputation levels found in patients on five different investigations are indicated in Table 2. It should be noted that Muller (1962) and Nathan &

Table 2 Levels of amputation in different investigations

	Forequarter	Above elbow	Below elbow
Muller 1962	5	31	26
Watkins Ford 1962	3	46	81
Nathan Davidoff 1963	—	19	17
Solonen <i>et al</i> 1965	—	24	48
Hansson 1967	—	16	52

Davidoff (1965) and Solonen (1965) performed their investigations on disabled soldiers. In the two remaining series—representative of a country in peace—there was a significant predominance of below elbow amputees. Extensive exarticulations of the shoulder joint are rare as these operations are mainly

advance in prosthetic research was made when a prosthesis model was introduced which could utilize the myoelectric signals for proportional control of pneumatic as well as electric power supplies (Bottomley 1962 Bottomley Kinnier Wilson & Vighlingale 1963) Bottomley & Coicell (1964) reported a method to obtain proportional control of a myoelectrically controlled split hook. Skin electrodes were used to receive myoelectric signals from the forearm extensors and flexors and the difference signal (Bottomley et al 1963) between the electrodes was utilized to control both the speed of movement and the force of grip when the hook opened and closed. This was achieved by two feed back signals one of which depended on the speed and the other on the force of grip. The clinical observation on which this solution was based is that a hand at work either opens or closes without using any force or grips with force without moving. The effect of the random variations on the myoelectric signals can be considerably reduced by applying a so called back lash generator (Bottomley et al 1963). This method permits a great variation in the myoelectric signals without reducing the ability to control the hand when loaded lightly. In Great Britain the technical development of this hand has been transferred to the Atomic Weapons Research Establishment but no clinical results of prosthetic applications on amputees have as yet been published.

In recent years it has been stated that an improved hand function can be obtained by certain elements of the electric hand prostheses performing automatically. An adaptive grip is offered (Tomovic 1961 1962 Palic 1964 1968) by placing several pressure sensitive transducers on the finger tips and palms of the hand which when activated transmit a feed back signal to the prosthesis. The hand will then automatically perform a number of standard movements depending on the transducers involved. This hand according to the latest modification can instead of the conventional stiff three finger grip perform a forceful grip towards the palm of the hand hook grip and clenching of the hand (Jmark 1968). Another type of feed back from the prosthesis to the carrier has been described where a pressure sensitive crystal situated on the prosthesis thumb gives an electric signal when deformed (Beeler During & den Hertog 1967). The purpose of this signal was to achieve cutaneous stimulation in one part of the body via surface electrodes. At present the advantage of the transmitted sensibility is being tested on a number of amputees. An extensive investigation of different methods to offer the amputee communication with the prosthesis via the tactile senses was recently published (Hiles 1968).

One of the primary problems arising in the development of myoelectric control systems is no doubt the lack of muscle control sites which has also been emphasized by Crock Wellman & Lyman (1962). The lack of sites is the fact that there are few places in the body where a control signal is available.

hension (*Lyman Groth & Heltman 1964*) So far nobody has managed to control three degrees of freedom (*Godden 1968* among others) despite many years research activities still going on in several laboratories

Geddes Moore Spencer & Hoff (1959) introduced the use of myoelectrically controlled orthoses Via myoelectric signals from a forearm muscle a pneumatic orthosis applied to a paralytic hand could be controlled Myoelectric control of electric orthoses has later been developed utilizing signals from a parietic muscle (*Haring & Nickel 1965 Antonelli & Haring 1967 Haring & Antonelli 1967*) The low level of myoelectric signals which can be picked up in severe paresis demands a high sensitivity of the amplifier in order to obtain a sufficient signal to noise ratio In connection with orthoses parietic muscles were electrically stimulated This method was initially utilized by stimulation of the peroneal nerve in hemiplegics with a drop foot (*Liberson et al 1961*) Electric stimulation of parietic muscles in the upper extremities was later described which enabled a parietic hand to perform an active movement (*Long & Masciarelli 1963*) In this case the parietic forearm extensors were electrically stimulated via skin electrodes and the hand splint fitted to the patient was closed by means of a spring The patient's active control over the so called electrophysiological hand splint was mechanical via remaining non parietic muscles of the shoulder Myoelectric control was later developed where instead of mechanical control the signals from intact shoulder muscles were utilized to control the hand splint (*Resnick & Iodornik et al 1964 Iodornik et al 1965*) The system was designed so that the amplitude of the myoelectric signals which were utilized as control signals were proportional to the amplitude of the stimulating impulse which affected the parietic muscle *Crochetiere Iodornik & Resnick (1967)* have shown that a rectified rectangular stimulating impulse is the most favourable and that the stimulating electrode should be large because of the muscular response to the stimulation *Iodornik Crochetiere & Resnick (1967)* also reported that the position of an extremity could be determined as a function of the amplitudes of the stimulating impulses

There are in principle two different methods of myoelectric control of prostheses on off or threshold control and proportional control In the first case there will be an indication if the signal amplitude exceeds a certain threshold level which is sufficiently high to prevent effectively disturbances caused by noise induction or resting potentials Proportional control implies that the signal is satisfactorily reproducible and that it will not be affected to a great extent by fatigue hysteresis or artefacts It has been pointed out that the intensity of the myoelectric signal on the whole varies continuously with the muscular tension (*Lippold 1952 Bigland et Lippold 1954*) Therefore if the myoelectric signal is only utilized for on off control of the prostheses a great deal of signal information will never be extracted An important ad

offer a solution to the control problem (Bottomley 1965 Scott 1966). Audial and visual feed back after training permits normal subjects to control up to three motor units in one muscle in a few cases even more (Basmajian Bae & Farivar 1965). Certain subjects can maintain the control over single motor units even without artificial feed back. The total number of units which can be activated irrespective of each other has not yet been determined. Using this method it is possible that several control sites can be obtained from a single muscle to control the prosthesis. Harrison & Mortensen (1962) believe that the frequency of the single motor unit activity also can be controlled voluntarily. Wagman & Pierce (1966) pointed out that with the technique described the remaining muscle is relaxed when the single motor unit is activated. No attention has been paid to the extent of which the single motor unit has participated in the total muscle contraction. Recently it has been pointed out however that subjects can be trained to maintain control over and alter the frequency of single motor units in a muscle even when certain disturbing movements occur in the extremity which is actuated by the muscle involved (Basmajian & Simard 1967).

Electromyography

During the middle of the 18th century the first reports were given of muscle contractions evoked by static electricity stimulation (Kraftenstein 1746). The most renowned investigation showing the connection between electricity and muscle contractions was a series of studies on frog muscle (Galvani 1791). The animal electricity was not believed by Galvani to originate from muscles but from nervous tissue particularly the brain. It was not until 1839 that it was shown that electric current really was developed in muscles (Matteucci 1844). The first to pick up electric current in active muscle contraction in man the first human electromyogram was DuBois Raymond in 1851 (Licht 1961). In the beginning of the 20th century improved methods were introduced inter alia by means of a string galvanometer (Einthoven 1901) which permitted rapid and sure recording of the weak electric activity accompanying muscle contraction.

Electromyography (EMG) the recording of an electric phenomenon in striated muscles was then employed mainly by physiologists. The first to apply this technique on pathological cases was Proebster who in 1928 studied a number of peripheral neuron lesions. At about the same time Adrian & Bronk (1929) introduced a concentric needle electrode to be inserted into the muscle. During the following years clinical electromyography was developed as a diagnostic aid in the studies of pareses and atrophy both of muscular (Lindsley 1929 Kugelberg 1947 1949) and neurogenic origin (Denny Brown & Lenny

reduces the possibility for the patient to communicate with the orthosis or prosthesis. It has been mentioned (Bottomley 1965 Scott 1966 1967) that to those who are severely handicapped unilateral or bilateral amputees, myoelectric control will be of the greatest advantage. The paradoxical situation then arises that the patients who are in the greatest need of a prosthesis with several degrees of freedom have a less number of well conducted muscle control sites available. It is obvious that the advantage of the normal hand as a gripping tool depends on its ability to perform in an adequate position (Capener 1960). A prosthesis with several degrees of freedom would therefore be desirable. The myoelectrically controlled hand prostheses available so far offer one function only—prehension—and no proportional control. By picking up three amplitude levels in the contraction of one separate muscle, two control sites will be available in one muscle (Dorcas & Scott 1966) and the demand of multiple control sites will be reduced. Only a little practice allows separate control of both functions, opening and closing of the hand. Scott (1966) mentioned that sufficient signals to control this three state unit can be picked up from partially denervated and atrophic muscles in amputees. Due to the lack of a description on the pathologically disturbed myoelectric signals, the magnitude of these changes cannot be assessed.

Programme coding of prosthetic function is another form of reducing the number of control sites for the control of complicated prostheses and orthoses. The prosthesis will then have certain automatic movements. A sequential coding equals a series of movements released by one single control site which technically can act very naturally (Maling & Clarkson 1963). This system however is slow and requires continual attention and cannot be unconsciously controlled by the patient. A better system is parallel coding where a number of control sites are activated in various pattern combinations synchronously. By comparing control signals, various codes in a pattern detector can be combined and the prosthesis can operate in several degrees of freedom simultaneously (Michael & Crauford 1963 Harrison 1964). This parallel coding will increase the number of functions available from a given number of muscles. Signals from strain gauges are sometimes used to indicate a muscle contraction instead of myoelectric signals (Lyman Groth & Weltman 1964). Attempts were made to obtain control of an arm simulator with three degrees of freedom (Lucaccini, Freedy, Rey & Lyman 1967).

Muscles which normally do not have any specific function, for instance the auricular muscles, can be trained to give voluntary contractions (Bontrager 1965). It is doubtful whether this type of myoelectric control will turn out to be of any practical value, since too much effort is demanded of the patient.

The fact that the human being can control single motor units voluntarily in a muscle (Harrison & Mortensen 1962 Basmajian 1963) was believed to

an individual motor unit are dispersed within an area constituting 17 per cent of the sectional area of the rat muscle with a considerable overlapping between different units. When a nerve impulse reaches the motor endplate where the terminal axon fibres are close to the separate muscle fibres the cell membrane of the muscle fibre will be gradually depolarized. At a certain level the action potential becomes released as a result of the instantaneous change of the membrane potential. This depolarization continues along the muscle fibre at a rate of 4–5 m/s in the human brachial biceps muscle according to Buchthal (1941) & Rosenfalck (1955) 3–4 m/s according to Stålberg (1966). The speed of dispersion along the muscle fibre becomes reduced in anaemia and at a low intramuscular temperature (Stålberg 1966). Following the depolarization of the muscle fibre membrane the muscle fibre contracts. The problem of the relation between excitation and contraction however is still not solved. The brief contraction of the individual muscle fibre lasts from 1 to 2 msec and during the same time an electric potential is spread in the surrounding tissues as a result of the depolarization. The existence of different motoneurons with different functions, so called phasic and tonic motoneurons, was demonstrated on cat (Cransit, Hnatovich & Steg 1956; Eccles, Eccles & Lundberg 1958). By means of histochemical methods it has recently been proved on rat that with respect to function there are different muscle fibres and motor units (Kugelberg & Edström 1964; Edström & Kugelberg 1965).

Motor Unit Action Potential Parameters

The purpose of diagnostic electromyography is to determine exact quantifiable and reproducible criteria of the myoelectric activity of the muscles in various clinical metabolic disturbances and diseases. For this quantitative measurements of various parameters of the individual motor unit potential have mainly been used such as duration, shape and amplitude. The parameter which is considered as the most favourable and also offers the best information in pathological conditions of the muscle is the duration of the motor unit potential. The duration of the motor unit potential is longer than that of the individual muscle fibre (Buchthal, Guld & Rosenfalck 1954). This depends on the muscle fibres of the same motor unit having a certain territorial dispersion and an almost simultaneous activation which results in a temporary dispersion. The electric potential which can be picked up from the motor unit has a duration of 7–8 msec in the human extremity muscles (Buchthal & Elmegren 1941; Lefter & Kugelberg 1949) and an amplitude between 0.1–0.5 mV. During latter years duration measurements according to typical criteria (Buchthal & Rosenfalck 1955) resulted in higher values, thus in the human brachial biceps a duration of 9–10 msec was reported (Kawser &

backer, 1938 Buchthal & Clemmesen 1941) Several compilations of the EMG changes, found by employing electromyography in different pathological conditions have been made (Wedell Feinstein & Pattle 1944 Buchthal & Pinelli 1952) With the increased information gained by electromyography this method has now become a clinical routine Furthermore during recent decades electromyography has come into use for anatomical and kinesiological studies of the muscular function (Basmajian 1967) Several surveys have been published (Kugelberg 1953 1959 Isch 1963 Buchthal 1957 1960 1961 Licht 1961 Basmajian 1967)

The Motor Unit

In the muscle the structural unit is constituted by the muscle cell or the muscle fibre The human muscle fibre varies considerably in length in different muscles the mean value being about 50 mm (Lindhard 1931) There is also a difference in diameter of the muscle fibres ranging from 0.03–0.1 mm with a smaller diameter in small muscles such as the external ocular muscles A number of muscle fibres are innervated by the same motor nerve fibre or axon originating from one anterior horn cell of the spinal cord This nerve cell with its axon and terminal branches as well as the innervated muscle fibres form an anatomical and functional unit the motor unit (Sherrington 1925) The nerve fibres divide close to the muscle fibres and do not spread over the entire muscle but the contact between the nerve fibre and the single muscle fibre occurs within the so called endplate zone in the middle area of the muscle fibre (Coers 1953 Coers & Woolf 1959) This endplate zone is well demarcated and constitutes less than 10 per cent of the total length of the muscle (Buchthal Guld & Rosenfalck 1955) The number of muscle fibres per motor unit differs considerably in each muscle Muscles controlling precise and rapid movements generally have the smallest number of muscle fibres per motor unit Thus in man there are ten fibres per unit in the tensor tympani muscle (Hersall 1955b) as opposed to 1600 in the medial head of the gastrocnemius muscle (Feinstein Landegard Nyman & Wohlfart 1955) The remaining muscles range between these extreme values

The muscle fibres belonging to one motor unit are dispersed over a certain area and mingled with fibres connected with other motor units demonstrated by means of a multi electrode technique elaborated by Buchthal Guld & Rosenfalck (1957) Fibres relating to the same motor unit have been demonstrated in circular areas with a diameter of 5–7 mm in the upper extremities and 7–10 mm in the lower extremities These areas allow space for muscle fibres from 15–30 different motor units (Buchthal Erminio & Rosenfalck 1959) Edstrom & Kugelberg (1968) recently reported that the fibres of

tion is obtained. This activity probably caused by mechanical irritation generally appears in showers (Buchthal & Clemmensen 1941) and sometime can be observed during several minutes (Petersen & Kugelberg 1949). When the muscle contraction is weak individual motor units are activated at the lowest possible frequency of 5-10 per sec. In higher muscle contraction more and more units are gradually activated and the discharge frequency of the individual unit increases in man up to approximately 50 per sec (Adrian & Bronk 1929). An average maximum frequency has later been indicated at 20 per sec (Wedell, Feinstein & Pottier 1944) and 25 per sec (Basmajian et al. 1965). As gradually more and more units are added a complex pattern is obtained and the individual motor unit potentials can no longer be identified.

Pathological Changes in EMG

Atrophy of the muscles and pareses of varying degrees may be caused by disease and damage affecting the lower motoneuron or the muscle. Both in neurogenic and myogenic pareses there are characteristic changes in the electromyogram with respect to the individual motor unit potential and the signal pattern on higher levels of contraction. This also applies to the appearance of spontaneous electric activity of the muscle. In peripheral motoneuron lesions with muscle denervation spontaneous fibrillar action potentials can be recorded from the relaxed muscle about 2-3 weeks following the lesion (Denny Brown & Pennybacker 1934). These potentials have a short duration of 1-2 msec and are considered to reflect the activity of individual muscle fibres. They appear at a low frequency. The fibrillation potentials however occasionally can be observed in non-denervated muscles. Consequently the finding of fibrillar action potentials must be carefully assessed in connection with the diagnosis. Another type of potential appearing in relaxed denervated muscles is repetitive with an introductory so called positive phase and a duration of 4-8 msec (Kugelberg & Petersen 1949, Jäpfer & Bullem 1945). In affection of the anterior horn cells of the spinal cord large polyphasic potentials appear corresponding to the fasciculation which can be seen with the naked eye (Pruessly & Buchthal 1963). In peripheral neuron lesion the number of activated motor units can be reduced at a maximum muscle contraction (Buchthal 1957). Often the activity does not fill the baseline and sometimes only single units are recorded. Furthermore in about 50 per cent of the cases the duration becomes prolonged (Buchthal & Clemmensen 1941) and usually there is an increase in the amplitude of the motor unit potential (Denny Brown & Pennybacker 1934). This can partly be explained by the regenerating nerve fibres not only contacting muscle fibres within their own motor unit but also others (van Harrell 1945) and by an in-

Petersen 1965) The duration of the motor unit potential varies considerably within different muscles. Muscles with fewer fibres per motor unit for instance the facial muscle have a decidedly shorter duration than muscles with more fibres per motor unit (*Petersen & Kugelberg 1949*). This can partly be explained by the reduced temporal dispersion which is found with a less number of fibres per unit (*Buchthal & Rosenfalck 1955*). The density of the fibres is of importance for the duration of the motor unit potential. The duration of the motor unit potential depends on the type of electrodes used which must be indicated and standardized (*Petersen & Kugelberg 1949*). With increasing age the mean duration of the potential will become prolonged (*Petersen & Kugelberg 1949*, *Buchthal & Pinelli 1952*). There will also be a prolongation of the mean potential duration when the intramuscular temperature drops (*Bentsen 1945*, *Buchthal & Pinelli 1952*). The same muscle reveals a deviating duration of various motor unit potentials as a result of different distances between the electrode and the endplate zone (*Buchthal Guld & Rosenfalck 1954*, *Kaiser & Petersen 1965*). A shorter duration has been indicated for the long head of the biceps muscle as compared to its short head (*Kaiser & Petersen, 1963*, *1965*). These authors stated that the mean duration is slightly longer for males than females.

The individual motor unit potential may appear in a mono bi or tri phasic form, depending on the type of electrode. Due to the scattering of individual fibres in the motor unit poly phasic potentials also appear and an increased spatial and temporal dispersion causes an increase in the number of poly phasic potentials (*Buchthal 1960*). In muscles where the motor unit potential has a long duration, there are thus more poly phasic potentials than in muscles with a short motor unit potential (*Buchthal Guld & Rosenfalck 1954*). The number of poly phasic potentials also increases pronouncedly at a low intramuscular temperature and also in connection with fatigue (*Buchthal Pinelli & Rosenfalck 1954*).

The third parameter studied in the motor unit potential is the amplitude. The amplitude is dependent on the fibre density and the number of muscle fibres of each motor unit and will increase linearly with the territorial magnitude of the motor unit (*Buchthal Erminio & Rosenfalck 1959*). The amplitude varies noticeably with the types of electrodes and the depths of insertion into the muscles i.e. the distance to the active muscle fibres. On the other hand it has been stated that the muscle temperature only has an insignificant effect and that fatigue does not at all affect the potential amplitude (*Buchthal Pinelli & Rosenfalck 1954*).

In a relaxed normal muscle no electric activity can be demonstrated (*Adrian & Bronk 1929*, *Landsley 1935*). When a needle electrode is inserted into a normal relaxed muscle a repetitive insertion activity of a short dura-

tion is obtained. This activity probably caused by mechanical irritation generally appears in showers (Buchthal & Clemmensen 1941) and sometimes can be observed during several minutes (Petersen & Augelberg 1949). When the muscle contraction is weak, individual motor units are activated at the lowest possible frequency of 5-10 per sec. In higher muscle contraction more and more units are gradually activated and the discharge frequency of the individual unit increases in man up to approximately 50 per sec (Adrian & Bronk 1929). An average maximum frequency has later been indicated at 20 per sec (Wedell, Feinslein & Pottle 1944) and 25 per sec (Basmajian et al. 1963). As gradually more and more units are added a complex pattern is obtained and the individual motor unit potentials can no longer be identified.

Pathological Changes in EMG

Atrophy of the muscles and pareses of varying degrees may be caused by disease and damage affecting the lower motoneuron or the muscle. Both in neurogenic and myogenic pareses there are characteristic changes in the electromyogram with respect to the individual motor unit potential and the signal pattern on higher levels of contraction. This also applies to the appearance of spontaneous electric activity of the muscle. In peripheral motor neuron lesions with muscle denervation spontaneous fibrillar action potentials can be recorded from the relaxed muscle about 2-3 weeks following the lesion (Denny Brown & Pennybacker 1938). The c potentials have a short duration of 1-2 msec and are considered to reflect the activity of individual muscle fibres. They appear at a low frequency. The fibrillation potentials however occasionally can be observed in non denervated muscles. Consequently the finding of fibrillar action potentials must be carefully assessed in connection with the diagnosis. Another type of potential appearing in relaxed denervated muscles is repetitive with an introductory so called positive phase and a duration of 4-8 msec (Augelberg & Petersen 1949, Jansz & Hull in 1941). In affliction of the anterior horn cells of the spinal cord large polyphasic potentials appear corresponding to the fasciculation which can be seen with the naked eye (Jansz & Buchthal 1941). In peripheral neuron lesions the number of activated motor units can be reduced at a maximum muscle contraction (Buchthal 1947). Often the activity does not fill the baseline and sometimes only single units are recorded. Furthermore in about 50 per cent of the cases the duration becomes prolonged (Buchthal & Clemmensen 1941) and usually there is an increase in the amplitude of the motor unit potential (Denny Brown & Pennybacker 1938). This can partly be explained by the regenerating nerve fibres not only contacting muscle fibres within their own motor unit but also others (van Marrewijk 1943) and by an in

creased synchronization (*Buchthal & Honckle 1944*) An early sign of re innervation may be the cessation of the fibrillation potentials or the appearance of poly phasic potentials (*Wedell Feinstein & Pattile 1944 Jasper 1946*)

In diseases of a muscle myogenic atrophy or pareses myosites or metabolic toxic and degenerative lesions of the muscles the motor unit becomes changed by a gradual destruction of individual muscle fibres while the number of motor units remains intact (*Kugelberg 1947 1949*) When the level of muscle contraction is high the number of motor unit potentials picked up is large in proportion to the pareses and fills the base line This is characteristic of advanced muscle dystrophy and is different from neurogenic pareses since in paresis of a corresponding degree a reduced number of motor units will be activated at maximum contraction The duration of the individual motor unit potential is often greatly reduced in myogenic pareses and moreover there is an increased number of poly phasic potentials (*Kugelberg 1947 1949 Buchthal & Pinelli 1952 Pinelli & Buchthal 1953 a*)

Frequency Analysis

Detailed investigations of the individual motor unit potential including duration measurements require that the level of contraction in the muscle be low In this case a few well isolated potentials can be picked up As the level of contraction rises an increasingly complex signal is recorded which unables further study of individual potentials The question then arises whether measurements of isolated potentials in connection with weak contractions will offer values representative of all motor units It is thus desirable to analyse the myoelectric signal for high levels of contraction also

Piper (1907) was the first to apply frequency analysis to the study of myoelectric signals in voluntary contraction He found that the signal amplitude varies regularly at a frequency of 47 to 50 Hz the so called Piper rhythm It was not until 1951 that the relation of various components in the power spectrum of the myoelectric signal was studied by a simple method (*Richardson 1951*) *Pichardson* determined the relation between power spectrum components above and below 400 Hz Increased signal activity at high frequencies was believed to indicate myopathy A frequency analyzer was first used to describe the power spectrum in detail both in normal and pathological cases by *Halton (1952)* The analysis of normals revealed a predominating activity between 100 and 250 Hz which gradually declined with increasing frequency and essentially vanished at 800 Hz It was only in the facial muscle and the small hand muscles that frequencies up to 1250 Hz could be observed In myopathy the predominating activity of the myoelectric signal was displaced towards higher frequencies Peripheral neuron lesions on the other hand

caused no changes in the power spectrum. The *c* results have later been confirmed (Fex & Arakawa 1957).

Neurogenic and myogenic atrophy were believed by these authors to change the shape of the power spectrum, particularly involving frequency displacements of the spectrum peak. A certain displacement toward higher frequencies could be observed in inactivation atrophy. This is in accordance with the fact that the duration of the individual motor unit potential is shorter in these cases (Buchthal & Pinelli 1952). Contrary to earlier investigations it has later been proved (Koppe & Hausman-Petrusewicz 1966) that in peripheral neuron lesions also the power spectrum of the myoelectric signals alters. Thus the spectrum will be more compressed and will decline rapidly both at low and—even more pronouncedly—at high frequencies.

The power spectrum of the myoelectric signal depends on the choice of electrode. The activity picked up with needle electrodes contains components of higher frequencies than that obtained with skin electrodes. This is partly due to the change imposed on the motor unit potential as it is transmitted through the tissues and picked up by a large electrode (Fex & Arakawa 1958). The power spectrum is also dependent on the positioning of the skin electrodes: the distance between the electrodes and the angle between the direction of the electrode and the muscle fibres (Sato 1964). As the electric fields in the various motor units differ in amplitude, phase, repetitive frequency and polarity, the individual motor unit potentials will add randomly at the electrode (Hays 1960). At higher levels of contraction the myoelectric signal therefore assumes the essential characters of noise. When the levels of contraction rise the motor unit potentials become synchronized, which results in increased potential duration and amplitude (Arakawa 1958). The low frequency components of the power spectrum are thus augmented. This synchronization, which has been described earlier (Buchthal & Clemmensen 1941) probably is the origin of the Laper rhythm. It has been stated that the predominant frequency of the power spectrum is different for different muscles (Sato & Tsurumizu 1967). These authors found the predominating frequency range of the human brachial biceps muscle to be 50 to 60 Hz, as opposed to that of the rat trochanteric muscle which was stated to be 100 to 200 Hz. Other authors have found the power spectra of the myoelectric signals in various muscles to be rather similar (Fex & Arakawa 1958). In Laper I (H Roberts, Kaiser, Mayerson & Petersen 1947) however a great number of statistically significant intermuscular differences have been demonstrated. Changes in shape of the low frequency portion of the power spectrum due to changes in contraction level have also been observed (Kaiser & Petersen 1963). Kaiser & Petersen (1963) were the first to find that the signal activity at frequencies exceeding 1000 Hz declined during a constant maximum contraction. They also intro-

duced a method of describing the profile of the spectrum with points in a frequency coordinate system *i.e.* loci. Six filters suffice to give an accurate description of the frequency profile.

Several investigations have been made dealing with the influence of fatigue on the appearance of the normal myoelectric signal. It has been pointed out that the signal pattern in isometric contraction probably deviates from that in ergometric work (Scherrer & Bourguignon 1959). In forceful isometric muscle contraction the myoelectric signal alters as a function of time during a prolonged contraction. The fact that prolonged muscle contraction reduces the amplitude of the motor unit potentials was mentioned as early as 30 years ago (Seiffarth 1940). Since then skin electrodes have been used to demonstrate that a fatiguing muscle contraction is accompanied by an increase in the myoelectric amplitude due to synchronization of the potentials. Consequently there will be a displacement of the power spectrum towards low frequencies (Scherrer & Bourguignon 1959). Frequency analysis also revealed that the amplitude increase in connection with muscle fatigue was concentrated to the low frequency part of the spectrum (Kogi & Hakamada 1962). These changes picked up by skin electrodes were considered to be caused by the synchronization of motor units. The existence of synchronization has been proved by means of cross correlation analysis (Person & Kudina 1968). An extensive investigation of dynamic changes in the power spectrum of the myoelectric signal during fatiguing muscle contractions was recently published by Kedefors Kaiser & Petersen (1968). During an isometric isotonic fatiguing contraction of the brachial biceps muscle there is a significant increase of the total myoelectric signal activity. The spectral changes are increased activity within the low frequency band and reduced activity within the high frequency band. These effects do not occur simultaneously and are probably of different origin. Synchronization and activation of further motor units may explain the total increase in the signal activity and a drop out of particular motor units may explain the reduced activity within the high frequency range. Analyses of high speed registrations of the myoelectric signal support this theory. These findings are of particular interest in conjunction with the previously mentioned possibilities of separating functionally different kinds of motor units.

Electrodes

Bioelectrical electrodes of various types are used for the following three main purposes: impedance measurement, bioelectric signal pick up and stimulation. In picking up myoelectric signals there are three methods of placing the electrodes on the skin: percutaneously and subcutaneously. The electrodes

employed are correspondingly called skin electrodes, percutaneous and implantable electrodes. In all myoelectric control systems so far introduced for clinical use, skin electrodes are employed and have been believed to be the only practical solution (Alter 1966).

There are two classes of skin electrodes: wet and dry electrodes. The dry ones consist of a metal plate fitted to the skin, whereas the wet ones are supplied with an electrolytic layer between the skin and the metal plate. This classification is not quite adequate since the dry electrodes also become covered with a thin electrolytic layer when they are applied to the skin. One disadvantage, which is more pronounced in dry than wet skin electrodes, is the high level of impedance, about 100 kohm. Thus a considerably higher input impedance—about 100 Mohm—is required of the amplifiers to prevent the attenuation and distortion of the myoelectric signal from exceeding permissible values (Ceddes, Baker & McGoodwin 1967). These high impedances may evoke interferences from the surroundings (Doreas, Libbey & Scott 1966). Impedance differences of the two signal electrodes may cause the amplifier to be charged with disturbing signals if its input impedance is not sufficiently high. Small movements between the skin electrode and the electrolytic layer may cause disturbances in the form of polarization potentials. This effect is particularly pronounced in the case of the formerly frequently used stainless steel electrodes (Fyllen 1959). Chloridized silver electrodes and a paste containing chloride ions, which permit ionic equilibrium, give a stable impedance and reduce the motion artefacts (Day & Lippitt 1964; Ceddes & Baker 1967; Jucels 1967). A method of reducing motion induced potential disturbances is to arrange a stable fixation between the electrode and the skin by means of a special paste container (Boter den Hertog & Kuypier 1966). The motion artefacts can also be eliminated by a conductive polymer bridge between the skin and the electrode (Thompson & Patterson 1963). One way of reducing the impedance between the tissue and the electrode—with a less disturbed signal as a result—is by using electrolytic paste to rub the horny layer of the skin with sand paper (Nightingale 1959). However, this is impossible if the electrodes are used daily in a prosthesis system. The electrolytic paste used with wet electrodes may cause problems due to allergic and toxic skin reactions. It is not probable, as Bottomley (1965) has pointed out, that the skin of the amputation stump could stand this for any length of time. Another problem connected with skin electrodes is that they pick up signals from a rather large area, and thus activity from neighbouring muscles also. It has been stated that when two antagonistic muscles are utilized for separate control functions, signals produced by one of the muscles should also be picked up by the electrode belonging to the other muscle (Scott 1967), resulting in so-called cross talk (Bottomley et al. 1963). It has been a subject

duced a method of describing the profile of the spectrum with points in a frequency coordinate system i.e. loci. Six filters suffice to give an accurate description of the frequency profile.

Several investigations have been made dealing with the influence of fatigue on the appearance of the normal myoelectric signal. It has been pointed out that the signal pattern in isometric contraction probably deviates from that in ergometric work (Scherrer & Bourguignon 1959). In forceful isometric muscle contraction the myoelectric signal alters as a function of time during a prolonged contraction. The fact that prolonged muscle contraction reduces the amplitude of the motor unit potentials was mentioned as early as 30 years ago (Seyffarth, 1940). Since then skin electrodes have been used to demonstrate that a fatiguing muscle contraction is accompanied by an increase in the myoelectric amplitude due to synchronization of the potentials. Consequently there will be a displacement of the power spectrum towards low frequencies (Scherrer & Bourguignon 1959). Frequency analysis also revealed that the amplitude increase in connection with muscle fatigue was concentrated to the low frequency part of the spectrum (Kogi & Hakamada 1962). These changes picked up by skin electrodes were considered to be caused by the synchronization of motor units. The existence of synchronization has been proved by means of cross correlation analysis (Person & Kudina 1968). An extensive investigation of dynamic changes in the power spectrum of the myoelectric signal during fatiguing muscle contractions was recently published by Kadefors, Kaiser & Petersen (1968). During an isometric isotonic fatiguing contraction of the brachial biceps muscle there is a significant increase of the total myoelectric signal activity. The spectral changes are increased activity within the low frequency band and reduced activity within the high frequency band. These effects do not occur simultaneously and are probably of different origin. Synchronization and activation of further motor units may explain the total increase in the signal activity and a drop out of particular motor units may explain the reduced activity within the high frequency range. These findings are of particular interest in conjunction with the previously mentioned possibilities of separating functionally different kinds of motor units.

Electrodes

Bioelectrical electrodes of various types are used for the following three main purposes: impedance measurement, bioelectric signal pick up and stimulation. In picking up myoelectric signals there are three methods of placing the electrodes on the skin: percutaneously and subcutaneously. The electrodes

employed are correspondingly called skin electrodes percutaneous and implantable electrodes. In all myoelectric control systems so far introduced for clinical use skin electrodes are employed and have been believed to be the only practical solution (Alter 1966).

There are two classes of skin electrodes: wet and dry electrodes. The dry ones consist of a metal plate fitted to the skin, whereas the wet ones are supplied with an electrolytic layer between the skin and the metal plate. This salication is not quite adequate, since the dry electrodes also become covered with a thin electrolytic layer when they are applied to the skin. One disadvantage, which is more pronounced in dry than wet skin electrodes, is the high level of impedance, about 100 kOhm. Thus a considerably higher input impedance—about 100 Mohm—is required of the amplifiers to prevent the attenuation and distortion of the myoelectric signal from exceeding permissible values (Geddes, Baker & McGoodwin 1967). These high impedances may evoke interferences from the surroundings (Dorcas, Libbey & Scott 1966). Impedance differences of the two signal electrodes may cause the amplifier to be charged with disturbing signals, if its input impedance is not sufficiently high. Small movements between the skin electrode and the electrolytic layer may cause disturbances in the form of polarization potentials. This effect is particularly pronounced in the case of the formerly frequently used stainless steel electrodes (Lykken 1959). Chloridized silver electrodes and a paste containing chloride ion, which permit ionic equilibrium, give a stable impedance and reduce the motion artefacts (Day & Lippitt 1964, Geddes & Baker, 1967, Facella 1967). A method of reducing motion-induced potential disturbances is to arrange a stable fixation between the electrode and the skin by means of a special paste container (Boter den Hertog & Kupper 1966). The motion artefacts can also be eliminated by a conductive polymer bridge between the skin and the electrode (Thompson & Patterson 1963). One way of reducing the impedance between the tissue and the electrode—with a less disturbed signal as a result—is besides using electrolytic paste to rub the horny layer of the skin with sand paper (Lightingale 1959). However, this is impossible if the electrodes are used daily in a prosthesis system. The electrolytic paste used with wet electrodes may cause problems due to allergic and toxic skin reactions. It is not probable, as Bottomley (1966) has pointed out, that the skin of the amputation stump could stand this for any length of time. Another problem connected with skin electrodes is that they pick up signals from a rather large area, and thus activity from neighbouring muscles also. It has been stated that when two antagonistic muscles are utilized for separate control functions, signal produced by one of the muscles should also be picked up by the electrode belonging to the other muscle (Scott 1967), resulting in so-called cross talk (Bottomley et al. 1963). It has been a subject

of discussion whether this cross talk actually does or does not consist of a simultaneous interference activity of the antagonist

In clinical electromyography needle electrodes of various types are routinely used to derive the myoelectric signal intramuscularly. The use of these electrodes may cause some discomfort and a risk of infection may arise when they are applied during long periods. For these reasons needle electrodes cannot be used in prosthetic control. A thin wire percutaneously run into the muscle is a new type of electrode which has many advantages (Scott 1965, Calduell 1967). Several methods of inserting these wire electrodes securely have been reported (Scott 1965, Parker 1968). Problems due to the segregating properties of the skin thus become eliminated but on the other hand activity only from a limited number of motor units in the muscle will be picked up. The range of muscle contraction available for recording will thus be reduced (Bigland & Lippold 1954). Another problem is the measures which regularly must be taken to prevent infection at the site of puncture. Still another is breakage of the wires. These problems were discussed by Scott (1966) who also suggested methods of reducing the complications. The helical percutaneous electrode designed by Calduell (1967) reduces the risk of wire breakage. This electrode offers the possibility of a more stable position as compared to other electrodes in recording how patients can learn by training to control single motor units in a muscle (Wagman & Pierce 1966, Calduell 1967). It has been stated that this type of training will provide amputees and disabled patients with greater possibilities of myoelectric control and thus render more sophisticated prostheses and orthoses feasible (Basmajian 1967).

In so called implant biotelemetry biological information from a part inside a living organism is wirelessly transmitted to the outside. Since 1954 when the transistor became commercially available and the development of microelectronics rapidly advanced biotelemetry has become an important tool in biological studies (Caceres, Cooper & Markey 1965). Implantable electrodes for the telemetry of myoelectric signals through the skin—by means of a frequency modulated wave detected by an external receiver—have been developed (Ao 1964, Hirsch, Kaiser & Petersen 1966). The main difference between these units is that Ao uses batteries as the source of energy whereas Hirsch *et al.* utilize externally generated inductive energy. Batteries have the drawbacks of being difficult to miniaturize and having short life. They must be exchanged at regular intervals which involve the disadvantage of repeated surgery. It has been stated however that an implanted battery can be inductively generated. This method allows a life of up to three years in a prosthetic system (Iodownik & Greene 1967). Important demands on an implanted electrode are tissue compatibility, stability and capability of providing reproducible signals. It should also be possible to sterilize and miniaturize the

electrode to such an extent that it will not affect the normal function of the muscle (Ho & Neuman 1967). Initial experiments on animals revealed that a capsule of varying thickness was formed around the implant and that infections and implant flaking could result (Grol Long Ion & Ho 1964). At the first implantations on man (Hirsch Kaiser & Petersen 1966) myoelectric signals containing more high frequency activity than those picked up with skin electrodes were obtained. The advantages of this type of signal had been stated previously (Hirsch Kaiser & Petersen 1964). The advantages of implanted electrodes as compared to other electrodes may result in isolated muscle activity with reduced cross talk or interference, a more favourable signal to noise ratio and a broader signal power spectrum. Recently several implantable electrodes for the telemetry of myoelectric signals have been designed. Implantation experiments primarily on animals are planned (Peilly 1968) and some results have already been published (Scott et al 1968, Tueler & Scott 1968).

The Information Content of Myoelectric Signals

As mentioned before myoelectric prostheses or orthoses can be operated in two ways by on/off or threshold control and by proportional control. The latter method requires that the salient signal parameter is reproducible and does not become affected by fatigue or artefacts. Scott (1968) inter alia discussed which property of the myoelectric signal should be selected to control the external system. The signal parameter chosen should be easy to utilize by the patient. As muscle tension can be controlled voluntarily it was natural to seek a parameter directly correlated to the developed muscle tension.

In respect of the choice of electrodes the myoelectric signal appearing at moderate levels of contraction reveals a complex pattern in which each motor unit is responsible for certain repeated activities. The character of the myoelectric signal accordingly is quite irregular and can only be described statistically (Basmajian 1967). Consequently several problems are involved if a single parameter of the myoelectric pattern related to total muscle tension is to be utilized for proportional control. Two separate parameters reveal the degree of muscle tension viz. the amplitude of the myoelectric signal and the firing frequency of the individual units. The most common description of a myoelectric signal so far has been to state the so called integrated mean value or root mean square (rms) value of the amplitude. This value is obtained by amplifying, rectifying and filtering the myoelectric signal. This signal processing is considered to yield a linear relation between signal amplitude and muscle tension in isometric contraction up to the maximum level of contraction (Hippold 1952, Lenman 1959). It has been discussed whether the

relation is linear at very small and high loads (*Nightingale* 1960). A large time constant of the filter will give a more even relation between the signal amplitude and the muscle tension. On the other hand in a myoelectric prosthesis system with feed back a large time constant will cause undesirable oscillations in the prosthesis (*Bottomley Kinnier Wilson & Nightingale* 1963). The time constant must be selected so that the delay introduced into the system will not seriously affect the patient's ability to control the prosthesis (*Bottomley & Couell* 1964). The relation between integrated signal amplitude and muscle tension in the upper extremities is not quite linear according to these authors. However they consider this to be of no importance when the signal amplitude is utilized as a control parameter.

In isotonic contractions the constant ratio between r.m.s. signal activity and tension is dependent on both the length of the muscle and the speed at which the muscle length changes as well as the direction of the change (*Bigland & Lippold* 1954). At constant speed the muscle tension increases linearly with the signal activity which in turn is more pronounced in a shortening than a lengthening of the muscle. In constant tension there is a linear relation between the signal activity and the speed in the shortening of the muscle but not in its lengthening. Muscle tension, speed and signal activity are thus related to each other. A difficulty arising when stump muscles in amputees are to be used as control sites is that these muscles are not distally anchored. The muscles will thus be unloaded during contraction and the speed cannot be assessed (*Alter* 1966).

When muscle contraction increases more motor units become activated and the single unit fires at a gradually higher frequency (*Basmajian Baeza & Fabrigar* 1965). The myoelectric signal can thus be described by measuring the frequency of the motor unit potential spikes in the signal pattern. There is also a relation between the frequency of spikes and the muscle tension (*Close Nickel & Todd* 1960). The r.m.s. signal amplitude is proportional to the square root of the frequency of spikes (*Basmajian* 1967) as long as fatigue or synchronization of motor unit potentials do not appear (*Bergstrom* 1959). The calculation of spikes has successfully been tried on normal subjects and *Scott* (1966) considered spike frequency to be a suitable control parameter in a myoelectric system.

In the rectified and filtered myoelectric signal there remain due to the statistical character of the signal variations in the mean value of the amplitude. These variations are suitably described as a disturbing noise. At low levels of contraction the noise is low but it increases gradually with the mean value of the signal amplitude. However the amplitude increases more rapidly with the result that the signal to noise ratio increases with an increased level of contraction. Not only the myoelectric signal but also background noise

which depends on several factors is picked up. Tissues and electrodes cause noise contributions the magnitudes of which depend on the respective impedances. There are also polarization potentials and motion induced potentials between the electrode and the skin (Nightingale 1959). Frequency analysis of this complex noise has proved it to be mainly confined to low frequencies (Nightingale 1959 Hayes 1960).

When the amplitude of the myoelectric signal is to be used as a proportional control parameter it is necessary to determine the number of clearly reproducible signal levels which can be activated irrespectively of each other (Lodovick & Kreifelt 1967). The number of levels depends on the level of contraction as discussed above and on the filtering of the myoelectric signals. At a very early stage it was pointed out that myoelectric signals for prosthesis control had to be filtered in order to reduce the disturbances caused by noise from electrodes and amplifiers (Batty, Nightingale & Willis 1955). These authors suggested 100–1000 Hz as a suitable range of frequency for the control signal. This range was later also recommended by Horn (1963). Below 100 Hz the background noise is too loud to be accepted. As the signal power spectrum decreases at higher frequencies deteriorating the signal to noise ratio the upper frequency limit in filtering the myoelectric signal was later reduced to 800 Hz by Bottomley, Kinnier Wilson & Nightingale (1963). The frequency range 300–1000 Hz has also been recommended with the object of excluding the fluctuations of the myoelectric signal believed to exist within the lower frequency ranges (Hirsch, Kaiser & Petersén 1964). Further knowledge is required to arrive at final recommendations on how myoelectric signals should be filtered. Thus it is necessary to learn the relation between developed mechanical force and various parts of the myoelectric signal spectrum.

Essentially our knowledge about the information content of the myoelectric signal is based upon normal subjects. In amputees and in patients with neurological disturbances there are deviations from the normal physiology which may be very important as has been pointed out by Hagman (1966). Thus there may be deviations in the nervous conduction rate in the appearance of motor unit potentials in the power spectra—static and dynamic—and in the effects of temperature deviations also.

SCOPE OF THE INVESTIGATIONS

The purpose of the present investigation has been to characterize myoelectric signals in order to create a basis for their utilization in prosthetic control. Myoelectric signals were analysed by employing previously introduced methods and methods especially developed for this purpose. These studies included clinical examination, conventional EMG analysis of myoelectric power spectra and analysis of the muscle control ability. Furthermore, various types of electrodes were studied. The attempt was to obtain a detailed characterization of myoelectric signals in normal and arm amputated males. The characteristics of the myoelectric signal thus obtained would increase the possibilities of optimizing the signal by suitable filtration.

- 1 In the stump muscles and the proximally situated muscles of arm and leg amputees there are frequently pathological changes in the appearance of the myoelectric signal as determined by conventional EMG (*Blom & Hagbarth 1964 Petersén 1966*). It was therefore necessary to carry out further studies on the appearance of the signals in a series of amputees.
- 2 The myoelectric signal must be filtered to obtain an undisturbed myoelectric prosthesis control, a fact pointed out earlier in the review of literature. Information of the shape of the myoelectric power spectra must be available for all the different muscles in normals and arm amputee.
- 3 Dynamic changes of the spectrum in fatiguing isometric muscle contractions were studied previously in normals (*Kadefors, Kaiser & Petersén 1968*) but must also be determined in arm amputees.
- 4 The relative properties of three different types of skin electrode, needle electrodes and a refined type of implantable electrode were studied.
- 5 Physiological deviations, for instance in speed and precision, must be borne in mind when a muscle is intended to be used as a control site in prosthesis control. Furthermore, the question arises whether an arm amputee will be able to use his stump muscle in performing rapid and well quantified muscle contractions. This ability may depend on whether the remaining muscles are normal or pathological according to the EMG findings. On the basis of these series of questions, an analysis of the muscle control ability was performed both on normal and arm amputated males by estimating their skill in manoeuvring an electro-mechanical apparatus by myoelectric signals.

METHODS

Electromyographic Methods

The electromyographic investigations were carried out by means of a 3 channelled DISA Electromyograph (Type 13 A 69). For the tests coaxial needle electrodes (DISA Elektronik 13 K 03) and skin electrodes (DISA Elektronik 13 K 62) were employed. The external diameter of the needle electrode is 0.65 mm and the surface of the internal platinum conductor at the tip is 0.07 mm². The external cannula of the needle electrode is made of stainless steel and well insulated from the internal thin platinum conductor. The skin electrodes are round metal plates (ϕ 7.5 mm) situated at a distance of 23 mm between the centre of each metal plate. The plates are covered with felt and at the examination the felt is moistened with electrolytical paste (Elema-Schonander Myograph Electrode Liquid).

The muscles were first examined in a totally relaxed resting position, then at slight voluntary contraction and finally at the maximum degree of contraction. The needle electrodes were inserted perpendicularly to the direction of the muscle fibres and in view of the existing anatomical variations they were placed at random in four different positions of each muscle at a depth of 0.2 cm. The individual motor unit potentials were studied on the screen of the oscilloscope using a sweeping speed of 1 mm/ms. In studying the motor unit potentials suitable amplifications were used: the deflection sensitivity was adjusted to values of 10 μ V/mm and in extreme cases it was 1000 μ V/mm. Film recording of myoelectric signals was performed at a film speed of 5 cm/s.

It would have been desirable to measure the duration of the single motor unit potential as this parameter is the most valuable in electromyographic diagnostics. However in several cases it was impossible to collect a sufficiently large number of single and well defined motor unit potential which covered the requirements of duration measurements (Buchthal & Clemmensen 1941, Petersen & Kugelberg 1949, Buchthal, Gull & Rosenfeld 1954). The reasons were that the remaining muscles in arm amputees often are very small and the patients sensitive to pricks and also that the skin in this area may be very thin and atrophic. According to the conventional clinical electromyographic method of examination both duration and amplitude as well as the number of phases of the individual motor unit potentials were assessed with the naked eye on the screen of the oscilloscope.

SCOPE OF THE INVESTIGATIONS

The purpose of the present investigation has been to characterize myoelectric signals in order to create a basis for their utilization in prosthesis control. Myoelectric signals were analysed by employing previously introduced methods and methods especially developed for this purpose. These studies included clinical examination, conventional EMG analysis of myoelectric power spectra and analysis of the muscle control ability. Furthermore various types of electrodes were studied. The attempt was to obtain a detailed characterization of myoelectric signals in normal and arm amputated males. The characteristics of the myoelectric signal thus obtained would increase the possibilities of optimizing the signal by suitable filtration.

- 1 In the stump muscles and the proximally situated muscles of arm and leg amputees there are frequently pathological changes in the appearance of the myoelectric signal as determined by conventional EMG (*Blom & Hagbarth 1964, Petersen 1966*). It was therefore necessary to carry out further studies on the appearance of the signals in a series of amputees.
- 2 The myoelectric signal must be filtered to obtain an undisturbed myoelectric prosthesis control, a fact pointed out earlier in the review of literature. Information of the shape of the myoelectric power spectra must be available for all the different muscles in normals and arm amputees.
- 3 Dynamic changes of the spectrum in fatiguing isometric muscle contractions were studied previously in normals (*Kadefors, Kaiser & Petersen 1968*) but must also be determined in arm amputees.
- 4 The relative properties of three different types of skin electrodes: needle electrodes and a refined type of implantable electrode were studied.
- 5 Physiological deviations, for instance in speed and precision, must be borne in mind when a muscle is intended to be used as a control site in prosthesis control. Furthermore the question arises whether an arm amputee will be able to use his stump muscle in performing rapid and well quantified muscle contractions. This ability may depend on whether the remaining muscles are normal or pathological according to the EMG findings. On the basis of these series of questions an analysis of the muscle control ability was performed both on normal and arm amputated males by estimating their skill in manoeuvring an electro-mechanical apparatus by myoelectric signals.

tensor muscles of the forearm. The temperature measurements were performed by means of the same thermo couple as mentioned before (FLLAB Type TE₃).

The power spectra were measured by means of a method and an instrument described by Kaiser & Petersén (1963, 1965). The method is based on transmission of the myoelectric signal through four octave bandpass filters centered at 50 Hz, 200 Hz, 800 Hz and 1600 Hz respectively. The four filter outputs are rectified and the resulting DC voltages are presented using the voltage from the 200 Hz filter as a reference. The three ratios obtained—power in the 200 Hz octave over power in the 50 Hz octave, power in the 200 Hz octave over power in the 800 Hz octave, and power in the 200 Hz octave over power in the 1600 Hz octave—provide a measure of the shape of the power spectrum.

The muscle action potentials are first amplified in a DISA Electromyograph, the output of which is fed to a specially designed spectrum analyzer. The output voltages are presented as the positions of two bright spots, the octave loci, on the screen of an oscilloscope. The horizontal deflections of the two spots are proportional to the 200 Hz/800 Hz and 200 Hz/1600 Hz activity ratios respectively. The vertical deflections of both spots are proportional to the 200 Hz/50 Hz activity ratio (Fig. 1). All three deflection sensitivities were 1 mm/dB.

Fig. 1. Loc. 1 graph. The vertical deflections of both spots are proportional to the ratio in dB of the activity (r.m.s. value) in the 200 Hz band to the activity in the 50 Hz band. The horizontal deflections are proportional to the ratio of the activities in the 200 Hz band to the 800 Hz band (circle) and to the ratio of the activities in the 200 Hz band to the 1600 Hz band (filled dot) respectively. The loci points in the figure pertain to the case of white noise.

The duration and number of phases of the individual potentials are affected by the intramuscular temperature which was measured in a stump muscle of 30 arm amputees. In below elbow amputees the temperature was measured in the remaining extensor muscle of the forearm; in above elbow amputees in the remaining brachial biceps muscle. These measurements were taken with a thermo couple needle from ELLAB, Copenhagen (Type TE₃). The needle has a diameter of 0.7 mm and is inserted into the centre of the muscle. The temperature was checked at the end of the examinations.

Power Spectra of Myoelectric Signals, Methods (Paper I)

Measurements of the myoelectric signal power spectra were performed on 50 healthy males aged from 20 to 50 years and on 30 amputated males of corresponding ages. To be included in the series it was necessary that the arm amputees were able to activate myoelectric signals up to a certain level. The myoelectric signals were picked up by means of coaxial needle electrodes. In cases of uninjured controls signals from eight positions of the needle in nine muscles of the right hand side extremities were analysed.

The following muscles were examined in succession: mm. biceps brachii, brachioradialis, extensor digitorum communis, deltoideus, trapezius, vastus lateralis, tibialis anterior, gastrocnemius and soleus.

The positions of the needle in the brachial biceps muscle were carefully defined in accordance with a procedure developed by *Kaiser & Petersen* (1965). The needle positions in the other muscles were not defined with this great accuracy. Still the needles were placed according to a consistent plan. In addition to the nine muscles mentioned above five other muscles were investigated. In 25 controls mm. biceps brachii, brachioradialis and extensor digitorum communis of the left side were examined. In all 50 controls four measurements were taken from the left side and four measurements from the right side of mm. *interosus dorsalis I manus* and *extensor digitorum brevis*. Needle positions in the latter two muscles were not selected to form any particular pattern.

In the case of arm amputees myoelectric signals from each muscle investigated were analysed for four needle positions only, as the stump region frequently is sensitive to pain and trauma. Due to anatomical variations between the arm amputees the needle positions could not be standardized.

In the cases of uninjured controls the temperature of the right brachial biceps muscle was measured in the endplate zone of the long head. For 20 of the controls the muscle temperature was measured in two definite points on the right side and in an endplate zone of the left side. The muscle temperature of the below elbow amputees was measured in the remaining ex-

muscle only could be studied. In two above elbow amputees and one below elbow amputee adequate myoelectric signals could not be picked up from the brachial biceps muscle. Where no signals were picked up the reason was either a lacking muscle or insufficient signal to noise ratio.

In accordance with the investigation on normal subjects performed by *Kalefors, Kaiser & Petersen* (1968) the purpose of this study on arm amputees was to measure quantitatively spectral changes within high frequency ranges during strong isometric muscle contraction and to measure the recovery rate of these changes.

A standard procedure was used for the examinations. Initially the patient performed two short forceful muscle contractions followed by an isometric muscle contraction—to the best of his ability—during 30 seconds and immediately afterwards two short contractions. After 30 seconds two short contractions were repeated and after a further 30 seconds two short contractions and so on. The recovery of the reduced signal amplitude within high frequency ranges which occurred during the persisting contraction was studied during at least 90 seconds. The standard schedule is illustrated by Figure 2 showing the signal amplitudes of two octave bandpass filters. In the following the designation $D_k = (S_{63} - S_{1000})_k$ expresses the difference in dB of the signal amplitudes for the octave band centered at 63 Hz and the octave band centered at 1000 Hz at a time indicated by k . The magnitude $S_{63} - S_{1000}$ was calculated for the moments indicated with arrows in Figure 2. Obviously the reduced magnitude of the signal activity within high frequency ranges can be calculated as $D_5 - D_{1+2+3}$ where D_{1+2+3} is the mean of D_1 and D_2 and D_3 . The recovery of the reduced magnitude of activity which occurred within high frequency ranges at different moments (k) is expressed by $D_5 - D_{k+1+2+3}$.

Fig. 2. The signal amplitudes showing activity (rms value) in the 63 Hz band and the 1000 Hz band during a maximum contraction ($k=3$) followed by a relaxation ($k=4$). The recovery is studied on the basis of brief contractions ($k=6$) and relaxation ($k=7$). From *Kalefors, Kaiser & Petersen* (1968) by permission.

The degree of muscle contraction was standardized with the aid of the contraction level indicator. The subjects were instructed to maintain for a few seconds the (moderate) contraction intensity yielding a specified volt meter deflection. During this period the loci coordinates were read—by the same person throughout the entire test series—from the screen of the oscilloscope.

In order to give a simple description of power spectrum shape in the standard terms of filter and circuit theory the three power ratios were transformed into three new variables. These approximate the spectra by a constant level and a straight line the high frequency asymptote which intersects the constant level at the so called corner frequency. The three transformed spectrum parameters are low frequency level (is 200 Hz level) high frequency asymptote slope and corner frequency. The statistical analyses were performed for both pairs of three parameters.

A detailed analysis of the measurement procedure indicates that the overall systematic error of the power spectrum values obtained is less than 1 dB. For further details of the procedure employed in describing the shape of the power spectrum and the statistical analysis involved see Paper I.

Dynamic Spectrum Analysis, Method and Instrumentation

Dynamic changes in the power spectrum of the myoelectric signal in a fatiguing isometric muscle contraction were analysed in different octave band pass filters by means of a broad band frequency analyzer (Bruel & Kjaer Type 2112) according to the method used by Kadefors, Kaiser & Petersen (1968). Following the notation of these authors the symbol S_f was used for the signal power expressed in dB within an octave band with a centre frequency of f Hz. The myoelectric signals were amplified in a DISA Electro myograph and then recorded on magnetic tape (Precision Instrument PI 200). The analysis of the spectrum was performed from the recorder. The different octave bandpass filters were switched in one by one and the signal amplitude (rms)—expressed in dB—was written by means of a level recorder (Bruel & Kjaer Type 2305). The error of the entire analysis was within ± 1.5 dB.

Needle electrodes of the same type as earlier were used for picking up the myoelectric signals and signals from several muscles were recorded for all but two of the 30 arm amputees. Among the below elbow amputees muscles on the extensor side of the forearm (closely corresponding to *m. extensor digitorum communis*) could be studied in 19 cases; this also applied to the brachioradial muscle. The remaining stump flexor muscles were studied in 12 cases. In 27 of the 30 arm amputees the brachial biceps muscle was examined. Five of these patients had been above elbow amputated and thus the remaining part of the

muscle only could be studied. In two above elbow amputees and one below elbow amputee adequate myoelectric signals could not be picked up from the brachial biceps muscle. Where no signals were picked up the reason was either a lacking muscle or insufficient signal to noise ratio.

In accordance with the investigation on normal subjects performed by Hadefors, Kaiser & Peterén (1969) the purpose of this study on arm amputees was to measure quantitatively spectral changes within high frequency ranges during strong isometric muscle contraction and to measure the recovery rate of these changes.

A standard procedure was used for the examinations. Initially the patient performed two short forceful muscle contractions followed by an isometric muscle contraction—to the best of his ability—during 30 seconds and immediately afterwards two short contractions. After 30 seconds two short contractions were repeated and after a further 30 seconds two short contractions and so on. The recovery of the reduced signal amplitude within high frequency ranges which occurred during the persisting contraction was studied during at least 90 seconds. The standard schedule is illustrated by Figure 2 showing the signal amplitudes of two octave bandpass filters. In the following the designation $D_k = (S_{63} - S_{1000})_k$ expresses the difference in dB of the signal amplitudes for the octave band centered at 63 Hz and the octave band centered at 1000 Hz at a time indicated by k . The magnitude $S_{63} - S_{1000}$ was calculated for the moments indicated with arrows in Figure 2. Obviously the reduced magnitude of the signal activity within high frequency ranges can be calculated as $D_5 - D_1$, where $D_{1,2,3}$ is the mean of D_1 and D_2 and D_5 . The recovery of the reduced magnitude of activity which occurred within high frequency ranges at different moments (k) is expressed by $D_5 - D_{k+1}$.

Fig. 2. The standard programme showing S_{63} (rms value) in the 63 Hz band and S_{1000} in the 1000 Hz band during a maximum contraction ($k=3$) followed by a relaxation period. The recovery is studied from the analysis of brief contractions ($k=1$) and compared to the initial state ($k=1-3$). From Kaiser & Peterén (1969) by permission.

Fig 3 Diagram showing the effect and recovery phenomena in a maximum muscle contraction. The abscissa shows increase in difference between the 63 Hz and the 1000 Hz components in dB. The ordinate shows the recovery state at a particular time instant. From *Kadefors, Kaiser & Petersen* (1968) by permission.

where $D_{k,k+1}$ is the mean of D_k and D_{k+1} . It is easier to explain this condition by a diagram (Fig 3). In this figure a value on an abscissa of 4 dB or less means that there is no significant reduction of the high frequency components. This value was obtained by calculating the statistical properties of the signal and by considering the error of method (*Kadefors, Kaiser & Petersen* 1968). The figure also illustrates that if the distance between a measured value and the line $D_5 - D_{1,2} = D_5 - D_{k,k+1}$ exceeds 4 dB, the recovery is not considered to be significant. The encircled point in the figure indicates a muscle contraction where the effect regarding the decay of high frequency components is significant but the recovery is not complete.

The values obtained from the amputees have been compared with the normal values stated by *Kadefors, Kaiser & Petersen* (1968). No mention is made as to which side was tested at the investigation but according to personal communication with the authors, all the signals were picked up on the right hand side. The purpose of the present investigation was to study the dynamic changes in the spectrum of myoelectric signals obtained from amputees in connection with fatiguing muscle contractions. Due to the limited number of observations of each muscle, the series was not divided into left and right hand sides nor into levels of amputation. A comparison with the normal series is despite this of importance as for practical reasons it is valuable to know any deviating dynamic changes of the spectrum in amputees before performing signal processing. Differences in muscle effect and recovery between normals and amputees were analysed by the ordinary *T* test.

Methods of Comparing Electrodes (Papers II, III)

Several methods have been used for comparison of the properties between different types of electrodes. In three commercially available surface electrodes for prostheses (Austrian Viennatone, Italian INAIL and the Russian) the impedance was measured as a function of frequency. The impedances of the electrodes were calculated by means of the voltage drop at a constant current.

of 10 μ A measured with the aid of a phase sensitive voltmeter (Solartron VP 250). All the recordings were performed with the electrode in a standardized position on the extensor side of the forearm. The ground electrode was placed on the flexor side and consisted of a large wet silver plate.

By means of a voltmeter (HP 425 A) differences between the half cell potentials of the electrodes were measured. These measurements were also performed in a standardized position on the extensor side of the forearm. Before the recordings the skin was carefully cleaned with alcohol and each type of electrode was tested ten times.

A comparison of the signal to noise ratio in dB between the different electrodes could be obtained by measurements performed on similarly placed electrodes on the forearm and at accurately controlled muscle contractions. By loading the finger extensors of the forearm with a constant rather small weight (1 kg) a comparable degree of contraction was obtained. As an amplifier a DISA Electromyograph was used and the 250 Hz octave band was selected for the analysis giving the best signal to noise ratio. The noise level was measured at complete relaxation and was reproducible to within 2-3 dB.

Some spectral characteristics obtained in the signal to noise ratio investigation were compared between the surface electrodes and an implanted electrode. The analysis was performed on an octave band analyzer (Bruel & Kjaer 2112).

Six electrodes for telemetry of the myoelectric signals were implanted on four voluntary subjects: two uninjured controls and two below elbow amputees. The operations were performed under local anaesthesia and the electrodes were placed subcutaneously above the fascia. A technical description of the electrode is given in Paper III. The subjects were observed clinically and the tissue reaction after removal of the electrodes was studied macro and microscopically. The following methods for analysis of the recorded signals were used: study via rectification and integration of the total signal, spectral analysis and study via graphic recording. In the present study analysis has been undertaken by using a tape recording velocity of eight times the play back velocity. All frequencies were thus divided by eight. A conventional ink jet recorder (ELEMA Schonander Mingograph 42) capable of writing frequencies up to some hundreds of Hz is adequate. Rectification and integration of the total signal and spectral analysis were performed with the same analyzer as used before (Bruel & Kjaer 2112). Furthermore spectral analysis was performed with the apparatus described by Kaiser & Petersen (1963, 1965).

Control Ability Test Apparatus and Procedure (Paper IV)

When a muscle is utilized as a control site for prosthetic control the fact that anatomical and physiological conditions differ between various muscles is of

importance. The distal extremity muscles often have a larger degree of innervation (Feinstein, Landegard Nyman & Wohlfart 1955) and thus their control is more appropriate as compared to proximal muscles. This is believed to cause differences in speed and fatiguability (Tergast 1873). The aim of this investigation was not to study the speed and dynamics of separate muscles in order to characterize a control site. The purpose was to get an idea of the ability to manoeuvre a specially designed electro-mechanical test instrument using myoelectric signals. This yielded knowledge of the ability of uninjured and arm amputated males to perform rapid and voluntary quantified muscle contractions.

In a preliminary investigation three muscles in 30 uninjured males aged between 20 and 50 years, were studied: *mm. extensor carpi radialis longus*, *deltoideus* and *vastus lateralis* (Paper IV). Based on the experience of this investigation the instruction of the test subjects was modified at the definite investigation. Thus a further series of 30 uninjured males—in the same age groups—was tested. The nine muscles included in the definite investigation were *mm. extensor carpi radialis*, *flexor digitorum sublimis*, *interosseus dorsalis I manus*, *biceps brachii*, *triceps*, *deltoideus*, *trapezius*, *vastus lateralis*, *tibialis anterior*. All these tests were performed on the right hand side.

In 30 arm amputees with varying levels of amputation a number of muscles were studied: the stump muscle on the extensor and flexor sides of the fore arm: *mm. biceps brachii* and *deltoideus*. The amputations were performed on the right hand side in 13 cases. The method does not permit any differentiation of the manoeuvrability between the right and left hand sides. Consequently there was no distinction made between the right and left hand sides in the amputation series.

Surface electrodes (DISA Elektronik 13 K 62) picked up the myoelectric signals which were amplified in a DISA Electromyograph before being connected to one of the inputs of the test instrument. A signal from a test programme—recorded on tape—was connected to the other input. The actual test instrument is electro-mechanical and the technical description of this and of the test programme is described in Paper IV.

Apparatus and Test Programme

The two input signals: the myoelectric signal and the programme signal are rectified and converted to pulses of a frequency proportional to the level of the input signals. The output pulses are connected to a stepping motor which runs forwards and backwards depending on which input signal has the highest amplitude. In the mechanical system the stepped motor activates a tiltable

Fig 4 The vestibulo mechanical apparatus with its frame and fly wheel as the test subject will experience the sway term during the course of examination. Below a tap recorder and the standard programme

frame which moves freely around a horizontal axis having moving increments of 17 milliradians per pulse constituting the so called primary movement. A cylindrical shaft is placed on the frame and when the frame tilts the shaft rotates thus causing the secondary movement. On the front end of the cylindrical shaft which protrudes through an aperture in the face plate of the apparatus there is a fly wheel with an outer diameter of 14 cm. The rate of angular acceleration of this wheel is 8 milliradians/ cc^2 per milliradian tilt of the frame. A mark on the wheel indicates the centre of the system (Fig 4)

importance. The distal extremity muscles often have a larger degree of innervation (Feinstein, Landegard, Nyman & Nohlfart 1955) and thus their control is more appropriate as compared to proximal muscles. This is believed to cause differences in speed and fatigability (Tergast 1873). The aim of this investigation was not to study the speed and dynamics of separate muscles in order to characterize a control site. The purpose was to get an idea of the ability to manoeuvre a specially designed electro-mechanical test instrument using myoelectric signals. This yielded knowledge of the ability of uninjured and arm amputated males to perform rapid and voluntary quantified muscle contractions.

In a preliminary investigation three muscles in 30 uninjured males aged between 20 and 50 years were studied viz. mm. extensor carpi radialis longus, deltoidus and vastus lateralis (Paper IV). Based on the experience of this investigation the instruction of the test subjects was modified at the definite investigation. Thus a further series of 30 uninjured males—in the same age groups—was tested. The nine muscles included in the definite investigation were mm. extensor carpi radialis, flexor digitorum sublimis, interosseus dorsalis I manus, biceps brachii, triceps, deltoidus, trapezius, vastus lateralis, tibialis anterior. All these tests were performed on the right hand side.

In 30 arm amputees with varying levels of amputation a number of muscles were studied: the stump muscle on the extensor and flexor sides of the fore arm, mm. biceps brachii and deltoidus. The amputations were performed on the right hand side in 13 cases. The method does not permit any differentiation of the manoeuvrability between the right and left hand sides. Consequently there was no distinction made between the right and left hand sides in the amputation series.

Surface electrodes (DISA Electronil 13 K 62) picked up the myoelectric signals which were amplified in a DISA Electromyograph before being connected to one of the inputs of the test instrument. A signal from a test programme—recorded on tape—was connected to the other input. The actual test instrument is electro-mechanical and the technical description of this and of the test programme is described in Paper IV.

Apparatus and Test Programme

The two input signals, the myoelectric signal and the programme signal, are rectified and converted to pulses of a frequency proportional to the level of the input signals. The output pulses are connected to a stepping motor which runs forwards and backwards depending on which input signal has the highest amplitude. In the mechanical system the stepped motor activates a tiltable

Fig. 6 Block diagram showing the function of the electro mechanical apparatus in principle. The interaction between the deviation of the frame and the angular deviation from the centre position of the fly wheel can be expressed as two successive time integrations. There are two visual feedbacks: the deviations of the frame and the fly wheel respectively.

Subjects were instructed about the purpose of the examination, the function of the instrument and the test procedure. They were then requested to try to maintain the frame in a horizontal position and the fly wheel in the centre by alternating activation and relaxation of the muscle to be tested. However, there are two differences in the methods of the preliminary (Paper IV) and the definite investigations. In the first place it was especially emphasized that the subjects should concentrate on the tilt of the frame and only in extreme positions should they pay attention to the fly wheel. Secondly, the subjects rested comfortably with their arms on a support at the definite investigation of the deltoid muscle. As a matter of fact, it proved difficult to relax the deltoid muscle with the arm hanging, as at the previous test.

The function measured by this apparatus is of course extremely complex. The relation between man and machine according to the above test is approximately illustrated in a block diagram (Fig. 6). The comparatively uncomplicated test programme resulted in the subjects' satisfactory control of the apparatus during the greater part of the test. The fly wheel deviated considerably from the centre during short periods only. The secondary movement, i.e. the position of the wheel, is characterized by an approximately normal distribution and the instability of the position of the wheel is best described by the standard deviation. To designate this complex function of the apparatus, the term *manoeuvrability* was introduced.

A study of the manoeuvrability of various muscles in both uninjured subjects and amputees was considered justified in view of the future prosthesis applications. The following questions arose at the definite investigation:

1. Does the ability to manoeuvre the apparatus myoelectrically differ between various arm muscles in healthy males?

At a certain adjustable angular deflection of the wheel, a micro switch is activated and its position is recorded continuously (ELEMA Schönander Mingograph 42). The error is chosen so that the error indicating switch is activated if the wheel deviates more than $\pm 90^\circ$ from the centre. The accumulated time, the so called off time, during which the position of the wheel lies outside the error limits is indicated on the recorder.

The test programme was tape recorded from a laboratory oscillator. For each test on each muscle the total time required was 260 seconds. The programme signal is connected to a loud speaker, one input of the apparatus and the recorder. To neutralize the great importance of the factor of adaptation the subjects were both at the preliminary and at the definite tests initially examined twice utilizing the same muscle. The difficulty factors of the test programme and the amplification of the DISA—apparatus were selected in a way which obviously permitted all the subjects to grasp quickly the principle of the programme and fulfil it with minor errors. In all the subjects the muscles were tested in sequences.

During the tests the subjects were comfortably seated in an adjustable chair with the possibility of relaxing completely (Fig. 5). A carefully elaborated standard procedure was followed at each examination. To begin with the sub

Fig. 5. A test subject sitting comfortably in front of the apparatus during the course of the manoeuvring test. To the left the DISA Electromyograph and to the right of the apparatus the recorder. Surface electrodes are used to pick up the myoelectric signal.

MATERIAL

The series included 30 males who had been arm amputated during the period 1934-1966. With the exception of five patients resident in Stockholm they all belonged to the Gothenburg area and received their prostheses at the Orthopaedic Clinic in Gothenburg. Males of ages ranging from 20 to 50 years were selected as the males in the control groups were of corresponding ages. No patients with congenital defects were included. As the purpose was to study changes in stump muscles following amputation only above and below elbow amputees were examined. No patients with fore quarter resections were included. In the series available no patients had exarticulations either in their wrists or their elbow joints. One bilateral arm amputee was included. As the deficiency in this patient was congenital on one side only the operated arm was examined.

Table 3 Level of amputation related to age

Age at examination	Above elbow	Below elbow	Total
0-		4	4
6-30	1	5	6
31-40			
36-40	1	1	2
41-50	3		3
46-50	-	8	10
Total		23	30

The series consisted of seven above elbow amputees and 23 below elbow amputees and the distribution of the levels of amputation in the various age groups is tabulated (Table 3). One third of the patients were aged between 20 and 30 years and one third between 45 and 50 years and the remaining patients were distributed between the two first age groups. As most of the patients were operated upon at hospitals in different parts of Sweden and abroad many years ago information about the technique used at the operation was in few cases only available.

The patient's age at the time of amputation and the number of years elapsed since can be studied in Table 4. Most of the patients were operated on between

- 2 If such a difference exists is it correlated to the proximal muscles as compared to the distal muscles?
- 3 Does the ability to manoeuvre the apparatus differ with respect to the remaining muscles in arm amputees being normal or showing a peripheral neuron lesion according to conventional electromyography?
- 4 Does the ability to manoeuvre the apparatus differ between healthy and arm amputated males with corresponding muscles?

Statistical analysis

The statistical methods used to evaluate the results from this investigation were designed separately for each of the questions at issue

The off times for the nine muscles of normal males were analysed by means of a two way analysis of variance mixed model where the muscles were considered as a fixed effect and individuals as a random effect. No replicates were made which means that the interaction cannot be tested. For physiological reasons however it can be assumed that the interaction effect is negligible. In order to fulfil the conditions of the analysis of variance it was performed on the natural logarithms of the off times. When the analysis of variance showed significant main effects Scheffe's *S* method was employed to compare individual contrasts.

The difference in off times between muscles in arm amputated males showing normal or pathological EMG was analysed statistically using the Wilcoxon Two Sample Rank Test on the original values. This method was chosen because of the rather limited number of observations which did not satisfy the conditions of the normal approximation.

The difference in off times between muscles in normal and arm amputated males was analysed by the ordinary normal test on the natural logarithms of the off times.

A 5% level of significance was used throughout. The statistical analyses employed are described in full detail in *Brounle* (1960).

In the remaining group of trauma it is mostly children and adolescents who are the victims for instance in blasting accidents when playing with explosive material. In 13 cases the right arm and hand were amputated and in 17 cases the left.

Despite long standing handicap most of the patients as a rule have a remaining phantom limb perception of the lost hand (Cronholm 1951). In 19 cases this perception did not cause any discomfort but in seven cases pain was experienced which the patient localized to the lost hand (Table 6). Besides this phantom pain four patients experienced a varying degree of pain in the stump. Of the patients claiming phantom pain four stated that it was gradually disappearing. Three patients mentioned that the actual phantom perception of the lost hand had become reduced. In 18 of the 26 patients who had a phantom perception there was a general tendency to perceive the entire hand while the remaining 8 only perceived part of the hand. Furthermore five patients claimed that the stump was extremely sensitive to cold.

Among the types of prosthesis the passive cosmetic hand predominates and in this series 18 patients use it regularly all day. The prostheses have been classified in active functional hand prostheses and hooks as opposed to passive prostheses of different types. Table 7 depicts the distribution of the

the ages of 11 and 30 years. This is in accordance with several earlier publications in which it was stated that arm amputations mainly strike young individuals. The number of years during which the patients in this series had been amputated are evenly divided into intervals of five years from one year up to 35 years. In half of the series the operation had been performed 10-20 years earlier.

Recent investigations show that the most common cause of arm amputations are traumatic injuries. As the congenital defects constituting the next largest etiological group of arm amputees were excluded from this series the traumatic causes predominate. This is seen in Table 5 in which the causes of amputation and the age of the patients are stated. Traumatic injuries occurred in 27 cases, tumours in two cases and infection in one case. Industrial and traffic accidents strike different age groups more or less at the same rate.

In the remaining group of trauma it is mostly children and adolescents who are the victims for instance in blasting accidents when playing with explosive material. In 13 cases the right arm and hand were amputated and in 17 cases the left.

Despite long standing handicap most of the patients as a rule have a remaining phantom limb perception of the lost hand (Cronholm 1951). In 19 cases this perception did not cause any discomfort but in seven cases pain was experienced which the patient localized to the lost hand (Table 6). Besides this phantom pain four patients experienced a varying degree of pain in the stump. Of the patients claiming phantom pain four stated that it was gradually disappearing. Three patients mentioned that the actual phantom perception of the lost hand had become reduced. In 18 of the 26 patients who had a phantom perception there was a general tendency to perceive the entire hand while the remaining 8 only perceived part of the hand. prostheses with regard to the level of amputation. A combination of two types of prosthesis was used by nine patients. A passive hook was exchanged for the cosmetic hand in certain activities. One above elbow and one below elbow amputee never used any prosthesis. Furthermore, there were two patients who only used their prosthesis at work. A third of the patients had tried but never learnt to utilize and appreciate an active prosthesis fitted by means of wires. Among the seven above elbow amputees, five patients use an actively controlled elbow joint and in addition to this a cosmetic hand. These patients could not accept two cables, one for elbow flexion and one for prehension. The fact that the patients do not utilize their active protheses may be due to the lack of specialized rehabilitation centres in Sweden for arm amputees. Seven patients stated that they are dependent on their prothesis.

In general few arm amputees regularly use their prosthesis. However, there are great variations in earlier published findings. *Muller* (1962) in his follow up of 64 arm amputees found that 29 per cent used their prosthesis regularly. *Nathan & Davidoff* (1965) stated that of 36 arm amputees, 14 never used their prosthesis. In the present series of 30 amputees, 25 use their prosthesis every day at work and at home. The fact that the series is a selected group in which the patients are of ages below 50 years may explain their using the prothesis. Due to the fact that every patient can receive a prosthesis free of charge in this country, a very detailed and individual technical fitting can be made. This may also explain the high frequency of prosthesis carriers.

When asked, 21 patients stated that they managed independently at work and at home. Light patients required assistance in tying their shoe laces, neck ties and in fastening buttons. Only one patient mentioned that he required help every day with his personal care. This patient was above elbow amputated and slightly mentally retarded.

Mental disturbances, mainly depression and a tendency to isolation, are common complaints, and two thirds of the patients had similar trouble during the first years after the amputation. On the other hand, there are only four patients who have remaining mental complications due to their handicap. However, all the patients have adapted themselves socially, except one who is a criminal.

As the patients are well taken care of and offered the possibility of learning a new job—at public expense often during several years—their social adaptation becomes facilitated.

RESULTS

Clinical Investigation

All the patients were subjected to the following clinical examination inspection palpation assessment of range of motion and force and testing of sensibility of the stump. The range of motion in the shoulder and the elbow joints and the pronation and supination were measured with a goniometer. The physical strength of the arm was compared with that of the uninjured side and classified as normal or considerably reduced. The sensibility of the stump was tested for pricks and touch and subjected to Weber's two point discrimination test according to the procedure emphasized by Moberg (1962 1963 1964). The sense of vibration was examined on all the stumps. The length of the amputation stump was measured. On the below elbow amputees the length on the dorsal side of the forearm from the tip of the olecranon was measured and likewise from the acromion on the lateral side of the stump in above elbow amputees. The lengths of the amputated stumps have varied considerably (Table 8).

Discussion

Among the below elbow amputees the stump generally was of a good shape but in six patients the stumps which were short revealed different degrees of flexion i.e. lengths below 10 cm. The patients with long below elbow

stumps nearly all had normal skin and thin short movable scars across the tip of the stump. However two of these patients with long below elbow stumps had larger scars in one case consisting of two skin grafts. In seven of the below elbow amputees with short stumps more than half of the cases had small areas of adherent thin skin. Two of these had excess skin which deformed the stumps and made them soft. These patients have had difficulties in getting a satisfactory prosthesis application. Only one patient with a short below elbow stump had a symmetrical stump with acceptable skin.

At the inspection five of the seven patients subjected to above elbow amputation were found to have considerably deformed stumps. The remaining muscles were small and retracted in these five patients and furthermore there were large scars to a great extent adherent to the subjacent bone. One of the above elbow amputees had a soft stump with an excess of skin.

Already at the inspection the remaining part of the extremity revealed considerable atrophy in several cases. In the below elbow amputees atrophy of the upper arm was found in six patients. However the shoulder muscles were not affected in these patients. Atrophy was present in all the above elbow amputees. Among these there were three cases with reduced shoulder muscles mainly including the deltoid muscle and the supraspinatus muscle. As all the above elbow amputees in this series except for one patient only utilize cosmetic hand prostheses atrophy will often set in due to inactivity.

Palpation

Besides the skin also the muscles and the other tissues were examined when palpating the stump. As has been pointed out earlier the above elbow amputees had considerably reduced stump muscles and the remaining part of the biceps muscle was retracted in all the cases but one. In the below elbow amputees the stump muscles were seldom reduced. Among the patients with long below elbow stumps the muscle was reduced only in three cases. Retraction of the stump muscle was found in two below elbow amputees.

In the below elbow amputees there were three cases of neuroma all originating from the median nerve. In the above elbow amputees two neuromas originating from the radial and axillary nerves were found. At the palpation all the neuromas were diagnosed due to pain or their considerable size. In that connection attempts were made to assess the patient's ability to contract the remaining stump muscles on the extensor and the flexor sides irrespectively of each other. Only in one below elbow amputee with an extremely long stump was this ability noticed without earlier training. As a whole the patients have clearly experienced their inability to contract the remaining muscles independently of each other and had a sensation of activity

ing the entire stump as a unit. The patients who perceive distinctly the opening and closing of their phantom hand no doubt found it easier to try to contract the remaining stump muscles independently.

Range of Motion

Three below elbow amputees and five above elbow amputees had impaired mobility of their shoulder joint on the amputated side. The rate of below elbow amputees with this impairment is smaller as compared to earlier investigations. Thus Solonen *et al* (1965) found impaired mobility of the shoulder joint in 27 per cent of 48 above elbow amputees and in 29 per cent of 24 below elbow amputees. This discrepancy is no doubt due to the low mean age of the below elbow amputees in this series while the mean age of Solonen's series of disabled soldiers was 45 years. Painful impaired motion of the shoulder joint was found in one patient only. The degree of limited motion was slight and in all the patients the range of abduction was at least 160° and the degree of rotation was a minimum of 120°.

Of the below elbow amputees 15 patients had a normal range of motion of the elbow joint on the amputated side. In a third of these patients impaired flexion was observed. This was pronounced only in three cases: 11° between 2° and 75°. Hyperextension between 20° and 30° was found in three patients. None of the below elbow amputees experienced pain when forcing the movements of the elbow joints which were all stable in an extended position. No radiographic examination was performed.

The remaining ability to pronate and supinate depended on the length of the stump (Table 9). In the cases where the length of the stump exceeded 15 cm all except two patients could rotate their forearm more than 90°.

Table 9 Range of movement pronation supination at different stump lengths

Total	-	6	10	16

stumps nearly all had normal skin and thin short movable scars across the tip of the stump. However two of these patients with long below elbow stumps had larger scars in one case consisting of two skin grafts. In seven of the below elbow amputees with short stumps more than half of the cases had small areas of adherent thin skin. Two of these had excess skin which deformed the stumps and made them soft. These patients have had difficulties in getting a satisfactory prosthesis application. Only one patient with a short below elbow stump had a symmetrical stump with acceptable skin.

At the inspection five of the seven patients subjected to above elbow amputation were found to have considerably deformed stumps. The remaining muscles were small and retracted in these five patients and furthermore there were large scars to a great extent adherent to the subjacent bone. One of the above elbow amputees had a soft stump with an excess of skin.

Already at the inspection the remaining part of the extremity revealed considerable atrophy in several cases. In the below elbow amputees atrophy of the upper arm was found in six patients. However the shoulder muscles were not affected in these patients. Atrophy was present in all the above elbow amputees. Among these there were three cases with reduced shoulder muscles mainly including the deltoid muscle and the supraspinatus muscle. As all the above elbow amputees in this series except for one patient only utilize cosmetic hand prostheses atrophy will often set in due to inactivity.

Palpation

Besides the skin also the muscles and the other tissues were examined when palpating the stump. As has been pointed out earlier the above elbow amputees had considerably reduced stump muscles and the remaining part of the biceps muscle was retracted in all the cases but one. In the below elbow amputees the stump muscles were seldom reduced. Among the patients with long below elbow stumps the muscle was reduced only in three cases. Retraction of the stump muscle was found in two below elbow amputees.

In the below elbow amputees there were three cases of neuroma all originating from the median nerve. In the above elbow amputees two neuromas originating from the radial and axillary nerves were found. At the palpation all the neuromas were diagnosed due to pain or their considerable size. In that connection attempts were made to assess the patient's ability to contract the remaining stump muscles on the extensor and the flexor sides irrespectively of each other. Only in one below elbow amputee with an extremely long stump was this ability noticed without earlier training. As a whole the patients have clearly experienced their inability to contract the remaining muscles independently of each other and had a sensation of activat

ing the entire stump as a unit. The patients who perceive distinctly the opening and closing of their phantom hand no doubt found it easier to try to contract the remaining stump muscles independently.

Range of Motion

Three below elbow amputees and five above elbow amputees had impaired mobility of their shoulder joint on the amputated side. The rate of below elbow amputees with this impairment is smaller as compared to earlier investigations. Thus Solonen *et al* (1965) found impaired mobility of the shoulder joint in 27 per cent of 48 above elbow amputees and in 29 per cent of 24 below elbow amputees. This discrepancy is no doubt due to the low mean age of the below elbow amputees in this series while the mean age of Solonen's series of disabled soldiers was 45 years. Painful impaired motion of the shoulder joint was found in one patient only. The degree of limited motion was light and in all the patients the range of abduction was at least 160° and the degree of rotation was a minimum of 120°.

Of the below elbow amputees 15 patients had a normal range of motion of the elbow joint on the amputated side. In a third of these patients impaired flexion was observed. This was pronounced only in three cases: 11 between 2° and 7°. Hyperextension between 20° and 30° was found in three patients. None of the below elbow amputees experienced pain when forcing the movements of the elbow joints which were all stable in an extended position. No radiographic examination was performed.

The remaining ability to pronate and supinate depended on the length of the stump (Table 9). In the cases where the length of the stump exceeded 1 cm all except two patients could rotate their forearm more than 90°.

Table 9. Range of movement pronation-supination at different stump lengths.

Length of stump, cm	Pronation-supination			Total
	< 4	4-30	> 90	
0-5	-	-	-	-
6-10	4	1	-	5
11-15	1	1	-	2
16-20	-	4	8	12
> 20	-	-	4	4
Total	7	6	12	25

Physical Strength

The physical strength in the shoulder muscles of the above elbow amputees was considerably reduced in three patients on the amputated side. The others had, despite existing atrophy, an almost normal physical strength. The force of extension in the elbow joint was considerably reduced in five below elbow amputees. The force of flexion of the elbow joint was considerably reduced as compared to the uninjured arm in six patients. Furthermore, in two patients the force in flexing the elbow joint was extremely reduced. The pronation and supination strength was almost intact in half of the patients with long stumps. The other below elbow amputees who had a remaining pronation-supination ability revealed varying strength which however was difficult to estimate when the stumps were short.

Sensibility

In all the patients a tuning fork (C 125) was used to check that the sense of vibration was normal. In 12 of the amputees there was reduced sensibility within different areas of the stump. In five of the cases the disturbed sensibility for pricks and touch was localized in grafts or large scars. All the above elbow amputees except one had impaired sensibility in areas of varying sizes. A pathological two-point discrimination as compared to the uninjured arm was found in 11 patients. In five cases the pathological two-point discrimination was also found only within areas of cicatrices or grafts. Among the other six patients two-point discrimination was measured to range between 30 and 40 mm in two cases. In four patients no two-point discrimination could be measured in the comparatively small areas involved. The size of the skin area where an impaired or a neutralized sensibility was found varied between 5 and 18 cm² and was situated within the distal part of the stump.

The clinical results are summarized in Table 10. The table shows that below elbow amputees with short stumps on the whole revealed numerous changes. The stumps were irregularly shaped, the skin was thin, often adherent, and frequently the sensibility was impaired. There was no pronation or supination left and the mobility of the elbow was reduced as the physical strength was impaired as a rule. Technically, it is always difficult to apply a prosthesis to a short stump. Due to the above-mentioned reasons, the changes among these patients further complicate a satisfactory fitting of the prosthesis. In patients with long forearm stumps these changes are only found occasionally. However, the length of the stump is decisive for the degree of rotation. The stumps of the above elbow amputees are all irregular and atrophic; often the skin is thin and the sensibility is disturbed. Despite this they have

a remarkably good and painless mobility of the shoulder joint and the physical strength is only reduced moderately

Electromyographic Results

The electromyographic results are indicated in Table 11. In the above elbow amputees three different muscles were studied and in the below elbow amputees six muscles. In some cases a muscle was excluded from the investigation as the remaining muscle, if any, could not be identified. Pathological changes of the myoelectric signals picked up from stump muscles were found in both above and below elbow amputees in 40 per cent of these muscles. The type of pathological changes in the myoelectric signal appeared as a peripheral neuron lesion in all cases except one. This patient had a serious infection which resulted in amputation due to gangrene. In the extensor muscle and the brachioradial muscle of the forearm stump there were EMG changes which could be interpreted as myopathy. However, similar changes are found in reinnervation.

In three cases of the above elbow amputees there was a typical peripheral neuron lesion present in the remainders of the biceps muscle and in two cases of the triceps muscle. Among the below elbow amputees there existed a peripheral neuron lesion in the brachial biceps in three cases and in the triceps muscle in two cases. The latter amputees obviously had lesions of the lower

motoneuron at a much higher level than that of the amputation. Peripheral neuron lesions were a common finding in the stump muscles of the below elbow amputees. This was observed in eight cases on the extensor side and in six cases on the flexor side of the stump. Thus, in one third of these patients the myoelectric signal was pathological in the extensor and the flexor stump

a remarkably good and painless mobility of the shoulder joint and the physical strength is only reduced moderately

Electromyographic Results

The electromyographic results are indicated in Table 11. In the above elbow amputees three different muscles were studied and in the below elbow amputees six muscles. In some cases a muscle was excluded from the investigation as the remaining muscle if any could not be identified. Pathological changes of the myoelectric signals picked up from stump muscles were found in both above and below elbow amputees in 40 per cent of these muscles. The type of pathological changes in the myoelectric signal appeared as a peripheral neuron lesion in all cases except one. This patient had a serious infection which resulted in amputation due to gangrene. In the extensor muscle and the brachioradial muscle of the forearm stump there were EMG changes which could be interpreted as myopathy. However similar changes are found in reinnervation.

In three cases of the above elbow amputees there was a typical peripheral neuron lesion present in the remainders of the biceps muscle and in two cases of the triceps muscle. Among the below elbow amputees there existed a peripheral neuron lesion in the brachial biceps in three cases and in the triceps muscle in two cases. The latter amputees obviously had lesions of the lower

Table 11 EMG findings in different muscles of the amputation side in relation to level of amputation

the extensor side of the stump and the triceps muscle. There were fibrillations in all these muscles and also spontaneous positive potentials of short duration. This patient was operated on two years ago. Fibrillar action potentials were found in one muscle of another patient who had been operated upon twelve years ago.

In addition to the cases in which was found a decided lower motoneuron lesion other deviations in the appearance of the myoelectric signal were observed. Thus there was an increased number of polyphasic potentials approximately 10-20 per cent in nine muscles as compared to the about 4 per cent commonly stated in the literature as normal for limb muscles. The increased rate of polyphasic potentials was present in the stump muscles of below elbow amputees except in one case. A further deviation from the normal EMG was the presence of monotonous motor unit potentials with a duration which was estimated to be slightly increased. Such potentials were observed in seven stump muscles of below elbow amputees and in two of above elbow amputees.

Figure 8 illustrates a number of potentials of short duration approximately 4-5 milliseconds and an increased rate of extremely polyphasic potentials. The potentials were picked up from the same needle position in the brachioradial muscle of a patient who had been amputated for gangrene caused by a septic embolus. The EMG findings could be indicative of myopathy but similar changes could be a sign of reinnervation. In view of the cause of amputation and of the fact that in this case there was myositis the change in the myoelectric signals was recorded as myopathy.

The electromyographic findings in the stump muscle on the extensor side of the forearm and in the brachial biceps muscle varied with the intramuscular

Fig 8. Fig 8a motor unit potential picked up from the brachioradial muscle in a below-elbow amputee. Needle electrode in the same position. The potentials of short duration and the extremely polyphasic potential.

muscles. These muscles constitute the muscle pair which so far have been commonly explored as control sites in electric hand prostheses. However the pattern of a peripheral neuron lesion only appeared in two cases in the brachioradial muscle.

Table 12 illustrates the EMG results and their distribution within various muscles of the same patient as related to the length of the stump. It can easily be seen that pathological changes of the myoelectric signals were found in both long and short stumps. The clinical changes as found in all the patients with short stumps are not in accordance with the pathological EMG changes. The table further shows that of all the muscles examined in the amputated extremity only ten below elbow amputees had EMG findings which could be considered as normal. In seven other patients a peripheral neuron lesion was found in one muscle only. Thus it could be stated that a fourth of the below elbow amputees had pathological myoelectric signals in at least two muscles of the injured extremity.

The three muscles which have been examined in above elbow amputees showed a normal EMG in one patient only. Three patients had a peripheral neuron lesion in one muscle. Half of the above elbow amputees had no normal myoelectric signals in two of the three muscles which are the most natural to use as control sites.

The changes in the myoelectric signals which are designated peripheral neuron lesions were usually moderate. Pronounced lower motoneuron lesion with remaining single large potentials were found in three cases only. This is illustrated in Figure 7 where only single very large potential were picked up from the stump muscle on the flexor side of the forearm in a patient with an extremely short stump. This patient also had a peripheral neuron lesion in

Fig. 7 - Advanced lower motoneuron lesion. The myoelectric signal was picked up by a needle electrode from a small remaining muscle on the flexor side of a short forearm stump. The single motor unit potentials were extremely large with an amplitude of about 4 mV.

the extensor side of the stump and the triceps muscle. There were fibrillations in all the e muscles and also spontaneous positive potentials of short duration. This patient was operated on two years ago. Fibrillar action potentials were found in one muscle of another patient who had been operated upon twelve years ago.

In addition to the cases in which was found a decided lower motoneuron lesion other deviations in the appearance of the myoelectric signal were observed. Thus there was an increased number of polyphasic potentials approximately 10-20 per cent in nine muscles as compared to the about 4 per cent commonly stated in the literature as normal for limb muscles. The increased rate of polyphasic potentials was present in the stump muscles of below elbow amputees except in one case. A further deviation from the normal EMG was the presence of monotonous motor unit potentials with a duration which was estimated to be slightly increased. Such potentials were observed in seven stump muscles of below elbow amputees and in two of above elbow amputees.

Figure 8 illustrates a number of potentials of short duration approximately 4-5 milliseconds and an increased rate of extremely polyphasic potentials. These potentials were picked up from the same needle position in the brachioradial muscle of a patient who had been amputated for gangrene caused by a septic embolus. The EMG findings could be indicative of myopathy, but similar changes could be a sign of reinnervation. In view of the cause of amputation and of the fact that in this case there was myelitis the change in the myoelectric signals was regarded as myopathy.

temperature according to Table 13. The table clearly shows that the intramuscular temperature had dropped in all muscles showing peripheral neuron lesions increased duration or a surplus of polyphasic potential. All the myoelectric signals regarded as normal were picked up in muscles with an almost normal temperature. In nine cases the intramuscular temperature was 36 C or more. Temperatures between 35 and 36 C were noted in fifteen cases. Six patients had a very low muscle temperature which may be due to traumatic injuries of the vessels. There was no close relation between the length of the stump and the intramuscular temperature. Of the six patients who had temperatures below 35 C one patient only had a stump shorter than 10 cm.

Power Spectra of Myoelectric Signals (Paper I)

Statistical analyses of variance reveal with respect to nine right side muscles of the uninjured controls statistically significant differences of the spectrum parameters of individuals as well as of muscles. This result holds for all the six spectrum parameters. The most important source of variation for all six parameters is to be found within the muscle. The next most important source of variation also for all six parameters is the difference between muscle. The least important factor—again for all six parameters—is interindividual variation.

The fact that interindividual variations are significant implies that individuals having high parameter values for one muscle have high parameter values for other muscles also.

Various muscle pairs were compared by means of the *T* method. The only pairs displaying no statistically significant spectrum parameter differences at all are *m. extensor digitorum communis* vs *mm. brachioradialis* and *deltoideus*. Nine muscle pairs show significant differences for two parameters only. The results indicate a higher low frequency content for the trapezoid muscle and a lower low frequency content of the soleus muscle. The *mm. brachioradialis* and *deltoideus* have the lowest numbers of statistically significant differences displayed by the individual muscles and *mm. soleus* and *gastrocnemius* have the highest numbers. The only muscle pair for which all six spectrum parameter differences are statistically significant is *m. gastrocnemius* vs *m. trapezius*.

The detailed investigation of needle position influence which was carried out for the brachial biceps muscle revealed with minor exceptions only no statistically significant differences. No significant differences at all were found between the average values of the long head and the average values of the short head.

The comparatively small coefficients of correlation between spectrum parameters indicating low frequency content and parameters indicating high frequency content may be a reflection of the existence of different types of motor units.

Also on the left hand side muscles of the uninjured controls the statistical analyses of variance showed significant differences between the mean values of individuals as well as of muscles. This result holds for all spectrum parameters. As for the right side muscles intramuscular variation is most important, intermuscular variation is next most important and interindividual variation is least important. The number of statistically significant intermuscular differences is larger for the left side than for the right side. It is interesting to note that statistically significant parameter differences between the

left and right sides of mm interosseus dorsalis I manus extensor digitorum brevis biceps brachii brachioradialis and extensor digitorum communis take place in the same direction

Temperature measurements revealed no discernible temperature dependence of the spectrum parameters in the long head of the brachial biceps muscle of the 50 uninjured controls. Temperature influence can neither explain the power spectrum differences between two needle positions in this muscle nor the difference between the left and right sides.

Comparison between muscles yielding normal and neurogenic EMG in amputees was performed for the right and left side respectively of the stump extensor muscles and for the right side of the stump flexor muscle. The analyses revealed statistically significant differences for all spectrum parameters except for one of the right side flexor muscle. Comparisons between muscles yielding normal EMG in amputees were carried out for mm biceps brachii brachioradialis and the stump extensor muscle of below elbow amputees. The analysis showed statistically significant differences between the mean values of muscles for all parameters except for one parameter of the left side. When muscles of amputees yielding normal EMG and muscles of uninjured controls were compared statistically significant differences between the parameter values were obtained. The significant differences for right side muscles deviated in the same direction as those of left side muscles. The low frequency content of the amputee muscles was without exception low. Temperature measurements were performed in the stump extensor muscle of 14 below elbow amputees. The low frequency content tended to decrease with temperature.

Dynamic Spectrum Analysis of Myoelectric Signals in Amputees

The dynamic spectral analysis of myoelectric signals from four different muscles in 27 arm amputees is tabulated in Tables 14 and 15. The percentage of recovered muscles was calculated on the number of cases where a significant effect of the high frequency decay was found. The percentage of non affected muscles was calculated on the total number of the muscles examined. The values obtained at examination of the amputees was related to the corresponding normal values earlier indicated by *Kadefors, Kaiser & Petersen* (1968) except for the muscles on the flexor side of the stump where normal values were lacking (Table 15).

Table 15 shows that there was a difference between the remaining extensor muscles of the forearm stump and the corresponding muscles in normal subjects with respect to the decay of the high frequency components. In 53 per cent of the amputees there was no significant decay as compared to 5 per cent

pattern as the three forearm muscles examined on normal subjects by *Kalefsky, Kaiser & Petersén* (1965).

The brachioradial muscle was studied on 19 arm amputees the number of which corresponded to that of the normal series. There was no significant difference at the 5% level in a *T* test between the amputees and the normal subjects either with respect to the effect or the recovery. The median value of the high frequency decay was 8 dB for the amputees and 11 dB for the normal subjects. The number of non affected cases was 16 per cent for the amputees and 10 per cent for the normal subjects. The effect seems to be lower for the amputees than for the normal series and the difference is almost significant (Fig. 10). The distribution of the normal series with a limit of significance corresponding to 2σ has been plotted. The figure shows that three values for the amputees lie on or below the 4 dB limit of significant muscle effect. In two of these cases there was advanced atrophy of the brachioradial

Table 15 Effect and recovery with respect to the high frequency band decay

M biceps med in normals	10	12	55	50	45	5

in the normal series. The significant effect revealed in the extensor muscle by the amputees however was quite comparable with that in the normal series (Fig. 9). There was no significant difference either in recovery. In this figure the distribution of the normal series was plotted including values within a limit of significance corresponding to 2σ . The figure shows that more than half of the values obtained from this muscle in amputees lie closely to the origin of coordinates. Despite the powerful contraction found on clinical examination and the good quality of the signal, as observed with the naked eye, these patients obviously could not contract the remaining muscle as much as normal subjects. Furthermore, one case with a muscle effect of -4 dB was excluded from the figure as an adequate contraction was not achieved. In principle the same result was obtained at the examination of the remaining muscles on the flexor side of the forearm stump as on the extensor side. Thus in 50 per cent of the amputees there was no significant reduction of the high frequency components in the myoelectric signals picked up from this muscle. In cases where a significant effect was obtained the recovery could not be compared with that of a normal series but in principle followed the same

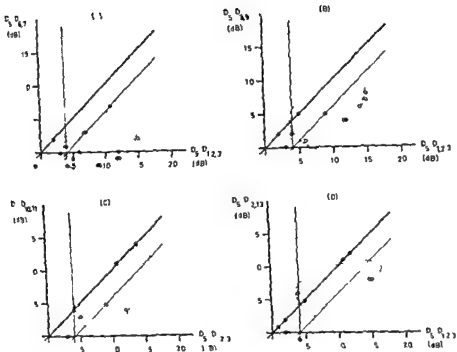

Fig 11 Diagrams identical with Figure 9 but showing the relationship between the actual value of $D_{5, D_{12,3}}$ and the value of $D_{5, D_{1,2}}$ at the needle electrodes. The dotted line represents the same limit of significance as in Figure 9.

percentage of cases without any significant muscle effect which corresponds to the normal subjects.

The results of the four muscles studied in arm amputees by the use of this method are not referred to the EMC findings. There was no point in making such a classification of the brachioradial muscle due to the few cases of pathological EMC findings. No significant difference was noted in the muscle effect and recovery of the muscles on the flexor and extensor sides of the forearm stump and of the biceps muscle as based on the EMC findings. As earlier the conclusions were made after performing a T test with the 5% level of significance.

Comparison between Electrodes and Implantation of Micro circuits (Papers II-III)

The importance of the three types of surface electrodes utilized in electrical hand prostheses were measured in different frequency ranges. The lowest importance was found in the Puzian electrode which is due to the use of

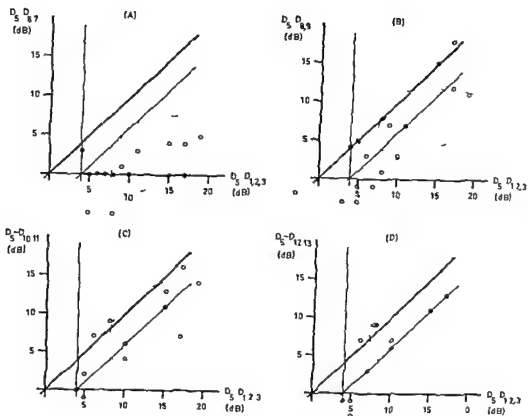

Fig 10 Diagram identical with Figure 9 but showing effect and recovery in the brachio radial muscle of 19 below elbow amputees needle electrodes The dotted line encircle normal values with the same limit of significance 2σ

muscle and a very reduced strength which involved difficulties for the patients to maintain maximal contraction during 30 seconds

The brachial biceps muscle was studied in 26 amputees five of whom were above elbow amputated. As the group of above elbow amputees was very small the observations were not referred to different levels of amputation. Table 15 shows that in comparison with the normal series there was no obvious difference in the high frequency decay. The muscle effect was 8.5 dB in the amputees and 10 dB in the normal subjects. A T test did not reveal any significant differences at the 5% level in effect and recovery (Fig 11). In 31 per cent of the amputees there was no significant muscle effect as compared to 5 per cent in the normal series. Among the five examined above elbow amputees three revealed no significant muscle effect which partly contributed to the high percentage of non affected cases. In two of the five remaining amputees where there was no high frequency decay of the biceps muscle there was a pronounced reduction of strength at flexion of the elbow joint. In three of the five cases no observations of any importance were made. This gives a

membrane sometimes was thin and pale and in others hyperaemic and thickened. The varying degrees of slight hyperaemia which could be found were not related to the period during which the electrodes were implanted. The histological examination revealed a capsule of connective tissue which had developed around the electrodes in varying degrees of thickness. There were layers of histiocyte cells on the surface and some foreign body giant cells and diffuse infiltration by lymphocytes as a sign of inflammatory reaction.

The myoelectric signals received from the implanted electrodes were all except in one case of a good quality. The reason of failure in this case was that a break down in the electronic circuit prevented the electrode from operating after the implantation. According to conventional electromyography the transmitted signals were normal and of a high quality. Repeated analyses proved that the myoelectric signals had been well reproducible during the periods of the experiments. This fact was also found by frequency analysis of the myoelectric signal. Even after several months the shape of the power spectrum was unchanged at different levels of contraction. As compared to needle electrodes a more favourable signal to noise ratio was obtained with the implanted electrodes.

The main problem of protecting the components of the micro circuit from surrounding tissues has been solved satisfactorily by the selected method of encapsulation. No technical failure was due to insufficient encapsulation in this investigation. However there were two cases of small cracks in the plastic material which allowed contact between the semi conductors and the surrounding tissue. The main failure was fatigue fractures in the gold wires at the surface of the plastic layer. These fractures prevented the myoelectric signals from being transmitted in three of the four cases where the electrodes had stopped operating. The fractures of the gold wires were verified radiographically. In one case the myoelectric signals could not be received due to defects in the external system. The external power supply was reliable. However the transmission of energy to the implanted electrode was rather sensitive to the relative positioning of the implanted and the external circuits.

Myoelectric Control of the Electro Mechanical Apparatus (Paper IV)

The results will be given in accordance with the questions discussed in the chapter of Methods. Table 16 illustrates the off times of nine muscles in a normal series of 30 uninjured males. The importance of learning in this type of test is illustrated by the difference between the off times of two successive tests of the same muscle. The results in Paper IV were thus verified between the two investigations with the exception of a small deviation of the mean in

electrolytic paste. The other electrodes, the Austrian and the Italian, are dry electrodes. The Italian electrode has a much higher impedance as compared to the Austrian as a consequence of its smaller area. All three types of electrodes have a rather high impedance which at 100 Hz exceed 100 kohm. The phase angle within the different frequency ranges has varied least in the Russian electrode.

The difference between the half cell potentials of the electrode pairs were measured. The maximum value of the polarization difference in a series of ten measurements was given for each type of electrode. It was obvious that wet electrodes had considerably higher polarization potential differences than dry electrodes depending on the abundance of dissociated ions which exist with the use of electrolytic paste. The polarization potential measured between the signal electrode and its ground plate in the Austrian electrode was considerably higher than the half cell potentials of the signal electrode pair. This fact was explained by the signal electrodes and the ground plate being made of different metals which have different contact potentials.

The signal to noise ratio in dB of signals from the electrodes under test was measured. The centre point distance of different electrodes and the area of the electrodes had a direct effect on the recorded signal to noise ratio. Thus, this ratio was the most favourable for the Austrian electrodes with the largest centre point distance and the largest picking up area. A large centre point distance will give a higher signal potential and furthermore signals from more motor units can be picked up with a large area of the electrode.

Spectral analysis of the signals picked up in the signal to noise investigation showed small differences between the spectra of the individual prosthesis electrodes.

Using intramuscular electrodes, needle electrodes and wire electrodes, a higher signal activity within the high frequency ranges was recorded as compared to skin electrodes. An implanted electrode had a power spectrum in between the intramuscular and the skin electrodes.

Six electrodes were implanted and worn by subjects for varying periods of up to 15 months (Paper III). The volunteers did not experience the short surgical procedures, implantation and extirpation of the electrodes as either unpleasant or painful. All the patients returned to full work the day after. The wounds healed without complications and the amputees could utilize their prosthesis without difficulty for their work and without the pressure from the prosthesis causing any discomfort. The final scars were thin and cosmetically quite acceptable.

After removal of the electrodes, they were all found to be encapsulated by a connective tissue membrane, sometimes slightly adherent to the skin but never to the subjacent fascia. Macroscopically, it was found that the covering

membrane sometimes was thin and pale and in others hyperaemic and thickened. The varying degrees of slight hyperaemia which could be found were not related to the period during which the electrodes were implanted. The histological examination revealed a capsule of connective tissue which had developed around the electrodes in varying degrees of thickness. There were layers of histiocytic cells on the surface and some foreign body giant cells and diffuse infiltration by lymphocytes as a sign of inflammatory reaction.

The myoelectric signals received from the implanted electrodes were all except in one case of a good quality. The reason of failure in this case was that a break down in the electronic circuit prevented the electrode from operating after the implantation. According to conventional electromyography the transmitted signals were normal and of a high quality. Repeated analyses proved that the myoelectric signals had been well reproducible during the periods of the experiments. This fact was also found by frequency analysis of the myoelectric signal. Even after several months the shape of the power spectrum was unchanged at different levels of contraction. As compared to needle electrodes a more favourable signal to noise ratio was obtained with the implanted electrodes.

The main problem of protecting the components of the micro circuit from surrounding tissues has been solved satisfactorily by the selected method of encapsulation. No technical failure was due to insufficient encapsulation in this investigation. However there were two cases of small cracks in the plastic material which allowed contact between the semi conductors and the surrounding tissue. The main failure was fatigue fractures in the gold wires at the surface of the plastic layer. These fractures prevented the myoelectric signals from being transmitted in three of the four cases where the electrodes had stopped operating. The fractures of the gold wires were verified radiographically. In one case the myoelectric signals could not be received due to defects in the external system. The external power supply was reliable. However the transmission of energy to the implanted electrode was rather sensitive to the relative positioning of the implanted and the external circuits.

Myoelectric Control of the Electro Mechanical Apparatus (Paper IV)

The results will be given in accordance with the questions discussed in the Chapter of Methods. Table 1b illustrates the off times of nine muscles in a normal series of 30 uninjured males. The importance of learning in this type of test is illustrated by the difference between the off times of two successive tests of the same muscle. The results in Paper IV were thus verified between the two investigations with the exception of a small deviation of the mean in

electrolytic paste. The other electrodes, the Austrian and the Italian, are dry electrodes. The Italian electrode has a much higher impedance as compared to the Austrian as a consequence of its smaller area. All three types of electrodes have a rather high impedance which at 100 Hz exceed 100 kohm. The phase angle within the different frequency ranges has varied least in the Russian electrode.

The difference between the half cell potentials of the electrode pairs were measured. The maximum value of the polarization difference in a series of ten measurements was given for each type of electrode. It was obvious that wet electrodes had considerably higher polarization potential differences than dry electrodes depending on the abundance of dissociated ions which exist with the use of electrolytic paste. The polarization potential measured between the signal electrode and its ground plate in the Austrian electrode was considerably higher than the half cell potentials of the signal electrode pair. This fact was explained by the signal electrodes and the ground plate being made of different metals which have different contact potentials.

The signal to noise ratio in dB of signals from the electrodes under test was measured. The centre point distance of different electrodes and the area of the electrodes had a direct effect on the recorded signal to noise ratio. Thus, this ratio was the most favourable for the Austrian electrodes with the largest centre point distance and the largest picking up area. A large centre point distance will give a higher signal potential and, furthermore, signals from more motor units can be picked up with a large area of the electrode.

Spectral analysis of the signals picked up in the signal to noise investigation showed small differences between the spectra of the individual prosthesis electrodes.

Using intramuscular electrodes, needle electrodes and wire electrodes, a higher signal activity within the high frequency ranges was recorded as compared to skin electrodes. An implanted electrode had a power spectrum in between the intramuscular and the skin electrodes.

Six electrodes were implanted and worn by subjects for varying periods of up to 15 months (Paper III). The volunteers did not experience the short surgical procedures, implantation and extirpation of the electrodes as either unpleasant or painful. All the patients returned to full work the day after. The wounds healed without complications and the amputees could utilize their prosthesis without difficulty for their work and without the pressure from the prosthesis causing any discomfort. The final scars were thin and cosmetically quite acceptable.

After removal of the electrodes, they were all found to be encapsulated by a connective tissue membrane, sometimes slightly adherent to the skin but never to the subjacent fascia. Macroscopically, it was found that the covering

test I This deviation may depend on a modified instruction to the patient before the definite examination. By changing the patient's position at the examination (see methods) obvious deviations were caused in the off times of the deltoid muscle on comparison between the two examinations. The test conditions were the same and comparable for *m. extensor carpi radialis longus* and for *m. vastus lateralis*. The off times of the *e* muscles—obtained at the two examinations—are in good accordance.

Table 16 shows that the trapezoid muscle deviated considerably from the other muscles. Furthermore, it is indicated in the table that there is a tendency towards lower mean values of off time for distal extremity muscles as compared to proximal, with the exception of the triceps muscle. However, it should be emphasized that there was a large dispersion for singular off times. The unexpectedly high mean value of the first dorsal interosseous muscle can perhaps be explained by the fact that it proved fatiguing and unnatural to abduct the forefinger continuously during several minutes.

The analysis of variance showed significant intermuscular and interindividual effects. The significance of the individual effect was weak, however. In

the first place this meant that the means of the natural logarithms of the off times of at least one muscle deviated from one or a few of the other muscles and secondly that there were also deviations between different individuals.

The analysis of variance did not show which mean values deviated from each other thus contributing to the significant muscle effect. When comparing different types of muscle contrasts it was found that the trapezoid muscle only had a significantly deviating mean value. In a histogram (Fig 12) this deviation is clearly demonstrated. The mean values of the other muscles were approximately on the same level. Thus there were no significant differences in the natural logarithms of the off times between the proximal muscles (mm biceps brachii, deltoideus, vastus lateralis) and the distal muscles (mm extensor carpi radialis, flexor digitorum sublimis, tibialis anterior). There is a certain difference in the natural logarithms of off times between the anterior tibial muscle and the lateral vastus muscle when illustrated in a histogram (Fig 13).

Fig 13 Histogram indicating a certain but statistically non significant difference in off times between a distal and a proximal extremity muscle of uninjured controls in the manoeuvrability. Based on the natural logarithms of the off times

the first place this meant that the means of the natural logarithms of the off times of at least one muscle deviated from one or a few of the other muscles and secondly that there were also deviations between different individuals

The analysis of variance did not show which mean values deviated from each other thus contributing to the significant muscle effect. When comparing different types of muscle contrasts it was found that the trapezoid muscle only had a significantly deviating mean value. In a histogram (Fig 12) this deviation is clearly demonstrated. The mean values of the other muscles were approximately on the same level. Thus there were no significant differences in the natural logarithms of the off times between the proximal muscles (mm biceps brachii, deltoideus, vastus lateralis) and the distal muscles (mm extensor carpi radialis, flexor digitorum sublimis, tibialis anterior). There is a certain difference in the natural logarithms of off times between the anterior tibial muscle and the lateral vastus muscle when illustrated in a histogram (Fig 13).

Besides the reservations made above all the off times obtained for the amputees were included in a comparison between uninjured controls and amputees as the EMG findings did not affect the manoeuvrability. Table 1, shows that in the group of arm amputees there were higher mean values of off time for each of the four examined muscles as compared to uninjured controls. This is clearly depicted in Figure 14. The normal test of the natural logarithms of off times showed however that this difference was significant only for the deltoid muscle.

The significant deviation—although slight—between different individuals verifies the clinical impression obtained during the experiments. A difference in dexterity was thus found but no systematical individual factor of importance was found at the statistical analysis.

The results of the examination in 30 arm amputated males are seen in Table 17. This table reveals that there were rather few values available for comparison between muscles with a normal EMG finding and those with a peripheral neuron lesion. The dispersion of the individual off times is large. The statistical analysis showed no significant differences with respect to the EMG findings for remaining extensor and flexor muscles and the brachial biceps muscle in below elbow amputees. In above elbow amputees the brachial biceps muscles could not be investigated statistically with respect to the EMG findings due to the small number of observations. Thus the off times obtained for the above elbow amputees from the brachial biceps muscle are excluded from the statistical analysis in a comparison between controls and amputees.

For further discussion see the text

used. Practical application of the electric hand prosthesis showed that the mechanical irritation existing with surface electrodes may cause sores if the sensibility of the stump is deficient. When the sensibility is normal and the subcutaneous tissue of the stump is satisfactory, dry skin electrodes will be tolerated even during long standing daily use. In many below elbow amputees the remaining pronation and supination cannot be utilized due to technical fitting problems of the prosthesis. In order to offer the patient a functionally improved prosthesis it would be desirable to achieve a normal positioning of the hand. That type of prosthesis should be possible to control with a minimum of effort and unconsciously after some time of practice. Perhaps an active pronation can be obtained with signals picked up from implanted electrodes in the pronator teres. Picking up separate activity from deep lying muscles, a possibility offered by implantable electrodes, is perhaps more realistic than creating control sites by other surgical procedures.

The impaired mobility of elbow and shoulder joints in a number of amputees is not of a magnitude which does prevent the use of a prosthesis. The physical strength is only in singular cases reduced to such an extent that it would be of any practical importance, especially as the prosthetic hand always will be the assisting hand in relation to the normal hand.

The myoelectric signals picked up from different muscles in an amputated arm are often pathological according to conventional electromyography. The changes—a peripheral neuron lesion in a large number of muscles—which were recorded in this series are in accordance with those found by *Petersen* (1966) in 50 arm amputees. The reason of this is probably due to the peripheral neuron being injured in connection with the trauma or at the operation. The extent of the pathological changes depends on the level at which the nerve has been damaged. Fibrillar action potentials rarely occurred which is due to the fact that most of the lesions antedated the examination by several years. In fresh amputated stumps denervation potentials probably appear much more often in muscles showing peripheral neuron lesions. In the remaining muscles of very short stumps large single potentials have been found in a few cases. This is probably a sign of a so called sprouting phenomenon which means that growing terminal nerve fibres belonging to a certain motor unit will contact muscle fibres belonging to another motor unit. The number of muscle fibres in a motor unit of that kind will become larger at the same time as the spatial dispersion increases. In practical application of simple electric hand prostheses with on-off control the interesting result was obtained that these large potentials were satisfactory as control signals. This is the more remarkable since only small potentials could be detected even when surface electrodes were used.

An increased motor unit dispersion due to sprouting results in more poly-

CONCLUDING REMARKS

During the latter decade myoelectric signals have been utilized in practice for control of electric hand prostheses and have furthermore served as control signals in stimulating paretic muscles. The investigations performed earlier involving a study of the myoelectric signal plotting of the control sites available and assessment of the ability to control man machine systems were based on normal subjects. However the myoelectric signals picked up from the patients who will utilize them in the future must be studied and accurately characterized. In this work the characteristics of the myoelectric signals in arm amputated males and normal individuals were investigated. The relative characteristics of different types of electrodes were examined. The description of the myoelectric signal thus obtained permits the signal to be optimized by suitable filtering before electronic application in prosthesis control.

It is the high unilateral and bilateral arm amputees who are in great need of multiple control sites to control prostheses with several degrees of freedom. Clinical findings revealed however that the stump muscles of above elbow amputees are atrophic and retracted and that the triceps muscle was absent in several cases. The shoulder muscles can also be considerably reduced. Asymmetrical shoulders and scoliosis of the thoracic spine are practically always present in above elbow amputees which was also pointed out by *Solonen* (1965). The result of these findings is unfortunately that only a limited number of control sites are available in above elbow amputees. It is possible that by attaching the stump muscles distally in order to prevent retraction and atrophy (*Weiss* 1960 1966) the functional end result will be improved. If the stump is not too short in below elbow amputees the muscles which are not retracted will only be slightly reduced. Anyhow it was found that these remaining muscles can be gradually retracted when they are continuously used to control an electric hand prosthesis. A myoplastic amputation procedure where the muscles are attached distally may also for this reason be more attractive. This procedure is believed to give a better stump with less pain, normalized circulation and temperature, less decalcification and a better skin (*Dederich* 1963).

The impaired sensibility which was noted in this series—especially in the above elbow amputees—must be considered if surface electrodes are to be

Kadefors, Kaiser & Petersén (1967-1968) modifications of the power spectrum due to sustained maximum muscle contractions were studied on amputees. The present investigation shows these modifications to be of such a magnitude that they should be taken into account in the design of myoelectrically controlled prostheses.

The other method Kaiser & Petersén (1963-1965) has been used in an extensive study (Paper I) of power spectra for moderate muscle contractions of short duration. This investigation demonstrated the existence of statistically significant intramuscular, intermuscular and interindividual power spectrum differences. The most important source of the differences consistently was intramuscular variation. This discovery further underlines the necessity of preprocessing the myoelectric signal in suitable filters. It also implies that individual alignment of these filters may be necessary in order to achieve optimum control.

In an investigation of three commercially available skin electrodes in myoelectric hand prostheses characteristics such as impedance, polarization, instability, signal to noise ratio and spectral properties were studied. In general it can be said that skin electrodes used in the control of myoelectric prostheses should have a low impedance, low polarization, instability, high signal to noise ratio and that the reproduction of the signal activity within high frequency ranges should be great. Furthermore the chemical and mechanical irritation of the skin should be insignificant. It is obvious that the electrodes which were available at this investigation did not fulfil the demands.

The results of micro circuit implantation show that the minor surgery required was easy to perform and caused no subjective discomfort. Implantation in the human being of the plastic material selected can thus be tolerated for at least one year. Due to the tissue reactions it would be justified to carry out further research work in producing more suitable material. Silicone rubber (Paper III) or ceramics (Jolly 1965) have been discussed. From the technical point of view no failure was due to insufficient protection of the components either mechanically or chemically. However there were small cracks in the plastic material in some cases which may have increased the tissue reaction. The myoelectric signals transmitted via the implanted electrodes were of a high quality and reproducible during long periods. Consequently it is obvious that the signals are not affected by the electrode being encapsulated in a connective tissue membrane.

The important failure found in this investigation was due to fatigue break down of the gold wires which maintained contact with the tissue. This problem can perhaps be overcome by using thinner flexible wires instead. As a result of our experience a modified electrode of that type has been designed. The

phasic potentials. Inactivation of motor units and synchrony of remaining units may according to *Pinelli & Buchthal (1953 b)* also contribute to the abundance of polyphasic potentials in lower motoneuron lesions. The low intramuscular temperature of the stump may also contribute to the increased number of polyphasic potentials by non synchronization of otherwise simultaneously activated muscle fibres within the same unit (*Buchthal, Pinelli & Rosenfalck 1954*).

In one single patient an EMG pattern of myopathy displaying a large number of short duration potentials and an excess of polyphasic potentials was observed. This patient probably had myositis in the stump muscles due to the serious arm infection which caused the amputation.

In the stump muscles potentials have also been observed with a certain—subjectively assessed—increased duration. These potentials were found when the intramuscular temperature was low. Several authors have shown earlier that a reduced intramuscular temperature causes an increase in the duration of the motor unit potential. This was believed to result from a decreased conduction velocity along the terminal branches of the nerve fibres and the muscle fibres (*Pinelli & Buchthal 1953 b*). The low intramuscular temperatures which are found in amputation stumps probably depend on a change in the circulation and comparatively reduced muscle bundles. *Eriksson (1965)* showed by means of angiography that the blood supply to leg amputation stumps may be irregular and that the muscle volume is reduced. The same author mentioned that the amputation stump painful to the patient had a greater mean blood supply at rest as compared to the cases without pain. Furthermore he pointed out that the abundance of serpentine vessels did not necessarily mean that the tissues are well nutritioned but that these vessels may act as shunts. This is also in accordance with the investigations of oxygen tension pO_2 present in the venous blood of amputation stumps (*Hullh & Hogstrom 1961*).

An essential point in myoelectric control of externally powered prostheses and orthoses is the dynamic range of the control i.e. the number of well defined separate levels of the output. Large dynamic output range requires that the full contraction range of the control muscle be utilized. Investigations on the properties of the myoelectric signal can thus not be limited to the individual motor unit potentials since these are discernible at the very weak contractions only. Even a slight increase of muscle contraction causes the myoelectric signal to take on the character of random noise. Thus the control properties of the myoelectric signal can be characterized throughout the dynamic range by means of its power spectrum.

Two definite methods have been used for measuring power spectra of myoelectric signals from a great number of muscles. With the aid of one method

There is no doubt a changed sensory information when part of an extremity is missing with an impaired ability to move the extremity with proximal muscles. This should be borne in mind as simulating tests with man machine systems are generally performed on normal subjects in prosthetic research. The results of these tests are not relevant for amputees with respect to certain muscles. An analysis necessary to obtain a myoelectrically controlled prosthesis with several degrees of freedom concerns the ability of a patient to utilize a number of control sites independently of each other. The activity present under normal daily and professional conditions in the muscles possible as control sites must be investigated. These complex functions must be subject to research before the possibility of controlling a prosthesis with signals from single motor units can be established.

favourable signal to noise ratio depends on the low noise contribution obtained by this method. Consequently the implanted electrodes are superior to the conventional ones especially at low contraction levels. A limited band width of the receiver has caused a reduced signal activity within high frequency ranges. An improvement can be achieved without difficulty by increasing the band width of the receiver. Both from the technical and the biological points of view, the existing miniaturization was adequate. Security of the function is however necessary during a considerably longer time which should be the aim.

When considering the function of the electro mechanical apparatus for the manoeuvrability test it can be assumed that the position of the fly wheel is characterized by an approximately normal distribution. The assumption that the position of the wheel is normally distributed gives a mathematically univocal relation between the off time recorded and the standard deviation. The instabilities of the input signals of the apparatus can be described by their standard deviations (standard deviation of programme signals = 0). The relation between the input and output standard deviations are functions of frequency inasmuch as rapid variations are damped and slow variations are stressed by the apparatus. This can also be described as a time delay of the apparatus. It is a general control system experience that time delays tend to create oscillations. The ability to manoeuvre the apparatus can partly be regarded as the ability to predict the next phase which is a cerebral function. The apparatus obviously does not separate the cerebral component and the muscle effect but measures a combination of these two factors. As a designation of this complex function the term manoeuvrability was introduced. The above reasoning reveals a relation between manoeuvrability and recorded off time.

The analysis of the ability to manoeuvre an electro mechanical apparatus by myoelectric signals shows that the trapezoid muscle differs from a number of extremity muscles. In that connection it should be noted that this muscle participates in the gross activities of the statics of the body. The endurance of the muscle is greater than its ability to perform rapid and precise movements. The difference in the number of muscle fibers per motor unit and in the existence of functionally different types of muscle fibers may explain this result of the trapezoid muscle. The moderate pathological changes present in the muscles of several amputees do not affect the manoeuvrability. These remaining stump muscles are thus cerebrally well controlled despite many years having elapsed since the normal function of the muscle ceased.

Arm amputees have greater difficulties to manoeuvre a man machine system with certain muscles as compared to normals. This can partly be explained by less daily activity and less training of the muscles on the amputated side.

There is no doubt a changed sensory information when part of an extremity is missing with an impaired ability to move the extremity with proximal muscles. This should be borne in mind as simulating tests with man machine systems are generally performed on normal subjects in prosthetic research. The results of these tests are not relevant for amputees with respect to certain muscles. ACKNOWLEDGEMENTS

This investigation was carried out at the Biomechanics Laboratory, Department of Orthopaedics, University of Gothenburg

I wish to thank Professor Carl Hirsch head of the Orthopaedic Department, for suggesting this subject to me giving me the opportunity of working in the stimulating and unconventional atmosphere which he has created, and for his encouragement and interest

During this investigation, problems obviously arose, and for the help in solving these I especially wish to thank Walter Brandt Engineer of AB Atomenergi Studsvik for his skilful work in designing the apparatus, Bernt Karlsson B A , for his patience in handling the data processing and Esbjorn Carlstrom, Ph D who supervised the statistical analyses

I am also grateful to my colleagues for their interest particularly Svanthe Rolander Ass Professor, who gave me impulses and good ideas, Hans Hellstrom, Engineer for his valuable assistance, Mrs Liva Rhedin Mrs Inga Lisa Elzer and Miss Lena Johnsson for technical and secretarial work

This investigation was supported by grants from

The Swedish Medical Research Council,
The University of Gothenburg
The Medical Society of Gothenburg
The Curt Trygger Memorial Fund
King Gustaf V Jubilee Fund
The Swedish Labour Market Insurance Society

Gothenburg in March 1969

ERLAND LYSELL

INTRODUCTION

Many people are occasionally or repeatedly subjected to pain and impaired motion in the neck often combined with radiating pain in the back of their head shoulders arms or chest In a Swedish population the percentage was stated to be 70 (Hult 1954)

These symptoms have been ascribed to various types of congenital degenerative or post traumatic changes of the cervical spine During latter decades numerous investigations have been published on the pathomorphology diagnostics and therapy

The diagnosis to the greater part was often based on studies of the function of the cervical spine It has been maintained that changes in the function either would be the cause of the disturbances or signs of processes which could result in pain However on perusal of the literature the information found about the normal function and its relation to degenerative changes is sparse This particularly applies to the pattern of motion

The purpose of this investigation was mainly to illustrate the normal pattern of motion and its variations due to degenerative changes by studying the possibilities of motion in an autopsy specimen series This study included all the interspaces between the second cervical vertebra and the first thoracic vertebra

REVIEW OF LITERATURE

A Earlier Methods for Measuring Intersegmental Motion in the Spine

1 Motion Studies on Autopsy Specimens

Ever since Galenus and Vesalius time the motion of the spine has been studied. This survey is limited to the in principle different methods reported and employed for intersegmental measurements of motion. For a comprehensive review of the literature the reader is referred to *Fluad* (1939) and *Andersson & Ekstrom* (1940).

The first real measurements were performed by *Weber* (1827). In three spinal specimens he dissected the spinal and transverse processes and inserted metal pins and then studied the motion of the pins while bending and stretching the specimens manually. The method of measuring angles or distances between pins inserted in the vertebrae has since then been employed repeatedly, inter alia by *Volkman* (1872), *Meyer* (1873), *Hughes* (1892), *Lovett* (1905), *Keene* (1906-07) and *Lucas & Bresler* (1961). *Ball & Meyers* (1964) used the method to study the cervical spine. They radiographed the specimen at maximal flexion and extension and measured the angle between the pins on the radiographs.

Lirchou (1928) studied the motion of the cervical spine in the sagittal plane in two specimens by making plaster impressions of the specimen in a neutral position and in manually caused flexion and extension. The specimens were macerated and split in the sagittal plane and placed in the different plaster impressions and the range of motion could be measured. *Voigrodsky* (1911) on four specimens demonstrated the intersegmental range of motion by testing the entire spine step by step as follows. A vertebra was fitted to a measuring apparatus and the superjacent vertebra was secured in a movable ring equipped with dials which indicated the motion at load in different directions.

The same method in principle was used by *Andersson & Ekstrom* (1940) for measuring motion in three thoracic and lumbar spine specimens. The recording was performed by means of a light ray which in small mirrors on the movable ring was reflected to a scale. Simul

TERMS AND DEFINITIONS

The terms and definitions mentioned below have been used throughout

The cervical vertebrae are numbered in the conventional way C2-C7

The first thoracic vertebra is designated Th1

An interspace is identified by the numbers of the two surrounding vertebrae, for instance C4/5

The motion of a segment is identified by the number of the vertebra above and the motion of this vertebra is always related to the subjacent one

Extension is equal to the motion in the sagittal plane dorsally directed

Flexion is equal to the motion in the sagittal plane, ventrally directed

Latero flexion is equal to the motion in the frontal plane to the right or the left

Rotation is equal to the motion in the horizontal plane to the right (clockwise) or to the left (anti clockwise)

The measuring points are designated A=anterior P=posterior R=right and L=left

For statistical analyses the Student's *T* test was used when no other indication is given

through the upper and lower contours of the vertebral bodies. If the endplates of the vertebral bodies appeared as ellipses he used their major axes as a measuring line. The maximum error was stated to be

2

Buettl Bauml (1954) used carbon paper to copy the contours of two vertebrae from the flexion radiograph to the extension radiograph and was careful to superimpose the two lower contours. The position of the upper two vertebrae corresponded to the motion. Lines were drawn through the posterior contour of the vertebral bodies and the angle between these lines indicated the range of motion.

For clinical use *Penning* (1968) placed a smaller film of the extension radiograph on top of the larger flexion radiograph. The contours of the two C7 views were made to coincide and he drew a line along the edge of the top film. This procedure was repeated for each vertebra. The angles formed between the lines represented the intersegmental range of motion.

Albers (1954) expressed the total motion of the cervical spine in the angle formed between two lines drawn through the posterior contour of C7 and C2. The intersegmental motion was illustrated by indicating the angle between the vertical axis of C7 and a line drawn from the point of intersection of this axis and the upper endplate of C7 to the centre point of the lower endplate of each vertebra. *Schalmt et al* (1958) who measured the motion of the lumbar spine in the sagittal and frontal planes, drew lines through the distal contour of the bodies. *Kottke & Mundale* (1959) used the same method in principle for the cervical spine while *Colachis & Strohm* (1965) measured the distance between the anterior and posterior corners respectively of the adjacent vertebral bodies. This is a mode of recording extension and compression of the anterior posterior parts of a disc in connection with motion. By means of cine radiography the ranges of motion in the atlanto occipital and the atlanto-ciphalic articulations were measured (*Fielding* 1957). Accurate measurements were difficult to carry out however due to the ever changing view and the enlargement (*Fielding* 1964 *Hirsch et al* 1964 *Penning* 1968).

B Pattern of Motion in Cervical Spine

The pattern of motion in the cervical spine depends on the structure and shape of the discs and the intervertebral joints and the combination of the changed positions which may appear. The system is also

aneously, the magnitude and direction of the loading force were recorded

Herne (1957) analysed the pattern of motion in the occipito atlanto-occipital joints by reading the movement direct on protractors, fitted to the specimen

The most accurate measurements of intersegmental motion were carried out by Rolander (1966) For his experimental study of the pattern of motion in the lumbar spine and the stabilizing effect of fusions he used extensometers, the movements of which were recorded by differential transformers

2 Motion Studies on Living Subjects

Direct measuring on living subjects by employing different types of goniometers, generally fitted to the head cannot and are not intended to reveal the motion of the individual segments This applies even if, for instance Stookey (1966-67) believed himself capable of determining intersegmental impairment of motion merely by means of manual examination Attempts have been made to record the motion of the individual vertebrae by fitting various types of indicators to the skin over the tips of the spinal processes (Lohr 1890, Lovett 1905) For several reasons this method must be extremely inaccurate and according to Lohr (1890) was not suitable for the cervical spine due to the comparatively great distance between the spinal processes and the skin

Radiography has so far, proved to give the best results when studying the motion of the spine in vivo Virchow (1928) was one of the first to use this procedure As a supplement to his earlier described investigation on specimens he examined one person by means of radiography Two radiographs were taken of the cervical spine one in flexion and one in extension From the radiographs he copied the vertebral bodies and the pedicles on a paper After selecting suitable measuring points he connected them by drawing lines When the two copies were placed on top of each other the deviating angles of the lines as seen on the copies could be measured Dittmar (1930) used the same method for the entire spine He completed the examination with a radiograph in neutral position and studied the latero flexion in the same way

In principle the same method was then used by many authors and has been called functional radiographic examination or 'Funktionelle Röntgenuntersuchung' (Penning 1968 Schmorl & Junghans 1951) The method of estimating the motion varies Bakke (1931) drew lines

through the upper and lower contours of the vertebral bodies. If the endplates of the vertebral bodies appeared as ellipses he used their major axes as a measuring line. The maximum error was stated to be 2° .

Buetti Bauml (1954) used carbon paper to copy the contours of two vertebrae from the flexion radiograph to the extension radiograph and was careful to superimpose the two lower contours. The position of the upper two vertebrae corresponded to the motion. Lines were drawn through the posterior contour of the vertebral bodies and the angle between these lines indicated the range of motion.

For clinical use *Penning* (1968) placed a smaller film of the extension radiograph on top of the larger flexion radiograph. The contours of the two C7 views were made to coincide and he drew a line along the edge of the top film. This procedure was repeated for each vertebra. The angles formed between the lines represented the intersegmental range of motion.

Albers (1954) expressed the total motion of the cervical spine in the angle formed between two lines drawn through the posterior contour of C7 and C2. The intersegmental motion was illustrated by indicating the angle between the vertical axis of C7 and a line drawn from the point of intersection of this axis and the upper endplate of C7 to the centre point of the lower endplate of each vertebra. *Schalinski et al* (1958) who measured the motion of the lumbar spine in the sagittal and frontal planes drew lines through the distal contour of the bodies. *Kottke & Mundale* (1959) used the same method in principle for the cervical spine while *Colachis & Strohm* (1965) measured the distance between the anterior and posterior corners respectively of the adjacent vertebral bodies. This is a mode of recording extension and compression of the anterior and posterior parts of a disc in connection with motion. By means of cine radiography the ranges of motion in the atlanto-occipital and the atlanto-epistropheal articulations were measured (*Fielding* 1957). Accurate measurements were difficult to carry out however due to the ever changing view and the enlargement (*Fielding* 1964 *Hirsch et al* 1964 *Penning* 1968).

B Pattern of Motion in Cervical Spine

The pattern of motion in the cervical spine depends on the structure and shape of the discs and the intervertebral joints and the combinations of the changed positions which may appear. The system is also

affected by the ligaments and the joint capsules. Thus, *Ball & Meyers* (1964) found close correlation between the range of motion and the extensibility of the posterior soft collagen structures.

In relation to its surface the cervical disc is comparatively high which according to *Fick* (1911) partly explains the large range of motion as compared to other parts of the spine. The two vertebral endplates are cranially convex in the sagittal plane, and caudally convex in the frontal plane and together with the disc form a saddle syndesmosis (*Fick*, 1911).

The surfaces of the intervertebral joints are almost perpendicular to the sagittal plane (*Fielding* 1964, *Penning*, 1968) and the mean inclination to the frontal plane is 45° . The cranial facets are directed backwards upwards and the caudal forwards downwards. The joint capsules are easy to extend and permit great mobility.

The following description of the pattern of motion is based on published reports of a few anatomical specimens (*Winslow*, 1730, *Weber* 1827, *Fick* 1911) and radiographs of subjects. With the exception of cineradiographic examinations (*Fielding* 1957 and 1964, *Jones* 1960) the reports are based on exposures in extreme positions and in a neutral position (*Dittmar*, 1931, *Bakke*, 1931, *Hadley* 1944 and 1956, *Exner* 1954, *Buetti Bauml* 1954, *Colachis et Strohm* 1965, *Penning* 1968).

In flexion a cervical vertebra tilts and slides forward over the subjacent one. There will then be a ventral compression and a dorsal expansion of the disc. The spinal processes are separated from each other and spread like a fan. Simultaneously the caudal intervertebral joint surface of the vertebra slides upwards forwards over the cranial joint surface of the subjacent vertebra. The joint space widens into the shape of a wedge with the base in a dorsal direction.

Most authors found that the tilting and sliding occurred at the same time. However *Jones* (1960) reported that flexion began with the tilting and the sliding followed later. In extreme flexion the joint facets were almost subluxated (*Fielding*, 1957) while *Penning* (1968) mentioned that they covered each other at least 5 mm.

When the cervical spine was extended the pattern of motion was reversed. On the other hand *Dittmar* (1931) stated that the C6 pattern was inverted inasmuch as at flexion it slid backwards and at extension forwards over C7.

The sliding combined with tilting caused the anterior and the posterior borders of the vertebral bodies in extreme positions to form an uneven curve and instead appear in a stepped shape. This sliding was

normal in the cervical spine but was believed to be a sign of disc degeneration in the lumbar spine (Annilsson, 1944)

The centre of motion is according to most authors placed in the body of the subjacent vertebra as opposed to other portions of the spine in which it is believed to lie in the disc (Fick 1911) According to Fick (1911) and Strasser (1913) the axis is in the centre of the vertebral body Penning (1968) mentioned that the axis of C2 is found in the postero caudal portion of the body of C3 but in the lower portions of the cervical spine its position gradually becomes more anterior. The axis of C6 lies in the centre of the upper C7 endplate. When Dittmar (1931) tried to construct the axis of motion he assumed it to lie within the disc. Thus he obtained different axes for different parts of motion. Exner (1954) and Hjortajo (1959) maintained that the axis is placed in the nucleus but according to Exner the nucleus moves towards the convex side during motion thus the axis of motion also moves. This seems to fit Iohaler's (1966) findings of a very large number of motion centres in the lumbar spine.

The movements in the frontal and horizontal planes are dependent on each other as latero flexion always is combined with rotation in the same direction and vice versa (Lott 1900, Vorogodsky 1911, Dittmar 1931, Exner 1954, Burtel-Bäumel 1954, Fielding 1964, Hin & Erdmann 1967, Penning 1968).

When a vertebra is latero flexed the disc on the concave side is compressed and expanded on the convex side and simultaneously distorted. On the concave side the caudal intervertebral joint surface slides backwards downwards and is pressed against the subjacent joint surface. On the convex side the joint surface slides upwards forwards and the joint space widens. Balke (1931) mentioned that the vertebral body in latero flexion slides on the disc slightly towards the convex side.

Even if the range of motion is reported merely as latero flexion or rotation the combined motion is optimal (Hjortajo 1959). Fick (1911) studied the planes of the intervertebral joints and found that an assumed line in the sagittal plane between the joint surfaces perpendicular to them would pass through the centre of the subjacent vertebral body. He believed this line to be the axis of combined motion the total range of motion around the axis amounting to 180°. Vorogodsky (1911) found that in two specimens the range was 76° and 154° respectively.

The lateral portion of the cervical spine the so called unco-vertebral region with the uncinate process thrusting upwards from the lateral

affected by the ligaments and the joint capsules. Thus, *Ball & Meyer* (1964) found close correlation between the range of motion and the extensibility of the posterior soft collagen structures.

In relation to its surface, the cervical disc is comparatively high which according to *Fick* (1911) partly explains the large range of motion as compared to other parts of the spine. The two vertebral endplates are cranially convex in the sagittal plane, and caudally convex in the frontal plane and together with the disc form a saddle synsidesmosis (*Fick* 1911).

The surfaces of the intervertebral joints are almost perpendicular to the sagittal plane (*Fielding*, 1964, *Penning*, 1968) and the mean inclination to the frontal plane is 45° . The cranial facets are directed backwards upwards and the caudal forwards downwards. The joint capsules are easy to extend and permit great mobility.

The following description of the pattern of motion is based on published reports of a few anatomical specimens (*Winslow*, 1730, *Weber* 1927, *Fick*, 1911) and radiographs of subjects. With the exception of cinematographic examinations (*Fielding* 1957 and 1964, *Jones*, 1960) the reports are based on exposures in extreme positions and in a neutral position (*Dittmar* 1931, *Balke*, 1931, *Hadley* 1944 and 1956, *Ezner* 1954, *Bueth-Baum* 1954, *Colachis et Strohm* 1965, *Penning* 1969).

In flexion a cervical vertebra tilts and slides forward over the subjacent one. There will then be a ventral compression and a dorsal expansion of the disc. The spinal processes are separated from each other and spread like a fan. Simultaneously the caudal intervertebral joint surface of the vertebra slides upwards forwards over the cranial joint surface of the subjacent vertebra. The joint space widens into the shape of a wedge with the base in a dorsal direction.

Most authors found that the tilting and sliding occurred at the same time. However *Jones* (1960) reported that flexion began with the tilting and the sliding followed later. In extreme flexion the joint facets were almost subluxated (*Fielding* 1957) while *Penning* (1968) mentioned that they covered each other at least 5 mm.

When the cervical spine was extended, the pattern of motion was reversed. On the other hand *Dittmar* (1931) stated that the C6 pattern was inverted inasmuch as at flexion it slid backwards and at extension forwards over C7.

The sliding, combined with tilting, caused the anterior and the posterior borders of the vertebral bodies in extreme positions to form an uneven curve and instead appear in a stepped shape. This sliding was

normal in the cervical spine but was believed to be a sign of disc degeneration in the lumbar spine (Knutsson 1944)

The centre of motion is according to most authors placed in the body of the subjacent vertebra as opposed to other portions of the spine in which it is believed to lie in the disc (Fick 1911) According to Fick (1911) and Strasser (1913) the axis is in the centre of the vertebral body Penning (1968) mentioned that the axis of C2 is found in the postero caudal portion of the body of C3 but in the lower portions of the cervical spine its position gradually becomes more anterior cranial The axis of C6 lies in the centre of the upper C7 endplate When Dittmar (1931) tried to construct the axis of motion he assumed it to lie within the disc Thus he obtained different axes for different parts of motion Exner (1954) and Hjortso (1959) maintained that the axis is placed in the nucleus but according to Exner the nucleus moves towards the convex side during motion thus the axis of motion also moves This seems to fit Rolander's (1966) findings of a very large number of motion centres in the lumbar spine

The movements in the frontal and horizontal planes are dependent on each other as latero flexion always is combined with rotation in the same direction and vice versa (Loret 1905 Voigrodsky 1911 Dittmar 1931 Exner 1954 Buettli Bauml 1954 Fielding 1964 Hin & Erdmann 1967 Penning 1969)

When a vertebra is latero flexed the disc on the concave side is compressed and expanded on the convex side and simultaneously distorted On the concave side the caudal intervertebral joint surface slides backwards downwards and is pressed against the subjacent joint surface On the convex side the joint surface slides upwards forwards and the joint space widens Bakke (1931) mentioned that the vertebral body in latero flexion slides on the disc slightly towards the convex side

Even if the range of motion is reported merely as latero flexion or rotation the combined motion is optimal (Hjortso 1959) Fick (1911) studied the planes of the intervertebral joints and found that an assumed line in the sagittal plane between the joint surfaces perpendicular to them would pass through the centre of the subjacent vertebral body He believed this line to be the axis of combined motion the total range of motion around the axis amounting to 180° Voigrodsky (1911) found that in two specimens the range was 76 and 154 respectively

The lateral portion of the cervical spine the so called uncovertebral region with the uncinate process thrusting upwards from the lateral

portion of the upper endplate differs in shape from other portions of the spine

It has been maintained that this region is a true synovial joint (Trolard, 1893, Compere *et al* 1958-59 Jackson, 1965) Most investigators however, are aware of the fact that changes simulating a joint, merely are very early fissures formed laterally in the annulus (Töndury 1943 1959, Hall, 1965, Ecklin, 1960 Hirsch *et al* 1967) These fissures may be an adaptation caused by motion in that area (Töndury 1943) The degenerative changes appear first in the cervical discs in this region (Hirsch *et al* 1967)

The uncinate process may be of importance for the pattern of motion in the cervical spine. It has been mentioned that the process prevents lateral or backward subluxation and serves as an obstacle of latero flexion. At the same time it acts as a guide rail for extension flexion (Frykholm 1951, Compere *et al* 1958-59, Ecklin, 1960, Penning, 1968)

C Range of Motion in Cervical Spine

The cervical spine is the most mobile portion of the spine. The mean range of motion is according to Hjortsjö (1959) extension 55° (if the motion between the occiput—C1-C2 is included 70°) flexion 65° (80°) latero flexion 15° (20°) at each side and rotation 45° (70°) in either direction. The individual variations are very large.

Measurements of motion were generally based on a neutral position. In specimens the neutral position was called *Eigenform* (Fick 1911) and was defined as the position of the cervical spine when it is unloaded and deprived of all musculature. The existing lordosis is believed to depend on the wedge shape of the discs with an anterior base and on the vertebral bodies being higher ventrally than dorsally.

The neutral position of living individuals is difficult to define. Many authors claimed that in the neutral position the vertebral bodies are situated in a symmetrical lordotic curve (e.g. Hadley 1949) Albers (1954) and Zeidler & Markuske (1962) found different types of neutral positions in different individuals. There is also a straight shape of no pathological significance. Fineman *et al*, (1963) showed that the normal lordotic pattern may be changed into a linear or kyphotic shape merely by lowering the subject's chin slightly at the examination. A comparison between different authors requires an accurately defined neutral position. However this is not the case. Albers (1954) and Dittmar (1931) stated a comfortable position. Penning (1968) pointed out that the lower

margin of the orbita should lie in the same horizontal plane as the external auditory meatus *De Sere et al* (1951) preferred that the occlusion plane of the teeth should be horizontal while other authors do not define the neutral position This variation may explain differences and statistical contradictions when the range of motion is classified in extension and flexion (Table 1) *Bakke* (1931) measured the extension to be four times the flexion while *Kottke et al* (1959) reported the flexion as slightly larger than the extension

The occipito atlanto axoid joints were obviously included in the clinical examination of patients Using goniometers of different types (*Bennet et al* 1963 *Buck et al* 1959) or other technical devices (*Holkmann* 1872 *Ferlic* 1962 *Schoening et Hannan* 1964) mean values were obtained on the whole in accordance with those of *Hjortskjov* (1959)

In order to demonstrate the intersegmental range of motion the most common method is to measure on radiographs Views of extreme extension and flexion and sometimes also a neutral position view have been compared Most authors expressed the total motion in the change of angle between the sagittal diameters of the top and the bottom vertebrae Others used the angle which is described by a line between the anterior corner of Th1 and C2 (*Colachis & Strohm* 1965) or the distance between the tips of the spinal processes (*Otto* 1955 *Rossler & Schmeisser* 1957-58) The results of the various methods are difficult to compare

An assessment of the entire cervical spine motion is for several reasons not sufficiently informative (*Kottke & Mundale* 1959) Segmental immobilization due to post traumatic or degenerative changes for instance may often increase the mobility of adjacent segments (*Fiedling* 1964) The intersegmental ranges of motion as reported in the literature are tabulated (Table 1) The few investigations carried out to the greater part deal with positions in the sagittal plane

The examinations of specimens are few and mainly of an early date The range of motion in the sagittal plane was measured on 18 specimens in the frontal plane on 5 and in the horizontal plane on 6 specimens

It is difficult to compare the results as the methods differ and as no details are given about the specimens *Ball & Meyer* (1964) who were responsible for half of the published series dealing with measurements in the sagittal plane radiographed the specimens in one plane They have not eliminated the sources of error which could be involved with this procedure

The intersegmental motion on living subjects was measured on radio

portion of the upper endplate differs in shape from other portions of the spine

It has been maintained that this region is a true synovial joint (Trolard, 1893, Compere *et al* 1958-59 Jackson, 1965) Most investigators however, are aware of the fact that changes simulating a joint, merely are very early fissures formed laterally in the annulus (Tondury, 1943 1959 Hall, 1965 Ecklin, 1960 Hirsch *et al* 1967) These fissures may be an adaptation caused by motion in that area (Tondury, 1943) The degenerative changes appear first in the cervical discs in this region (Hirsch *et al* , 1967)

The uncinate process may be of importance for the pattern of motion in the cervical spine It has been mentioned that the process prevents lateral or backward subluxation and serves as an obstacle of lateral flexion At the same time it acts as a guide rail for extension flexion (Frykholm 1951, Compere *et al* , 1958-59, Ecklin 1960 Penning 1968)

C Range of Motion in Cervical Spine

The cervical spine is the most mobile portion of the spine The mean range of motion is according to Hjortsjö (1959) extension 55° (if the motion between the occiput—C1—C2 is included 70°) flexion 65 (80°) lateral flexion 15° (20°) at each side and rotation 45° (70) in either direction The individual variations are very large

Measurements of motion were generally based on a neutral position In specimens the neutral position was called 'Eigenform' (Fick 1911) and was defined as the position of the cervical spine when it is unloaded and deprived of all musculature The existing lordosis is believed to depend on the wedge shape of the discs with an anterior base and on the vertebral bodies being higher ventrally than dorsally

The neutral position of living individuals is difficult to define Many authors claimed that in the neutral position the vertebral bodies are situated in a symmetrical lordotic curve (e.g Hadley 1949) Albers (1954) and Zeidler & Markuske (1962) found different types of neutral positions in different individuals There is also a straight shape of no pathological significance Fineman *et al* (1963) showed that the normal lordotic pattern may be changed into a linear or kyphotic shape merely by lowering the subject's chin slightly at the examination A comparison between different authors requires an accurately defined neutral position However this is not the case Albers (1954) and Dittmar (1931) stated a comfortable position Penning (1968) pointed out that the lower

graphs The table shows that the largest range of motion in the sagittal plane almost regularly was found between C5-C6 This was verified by other authors omitting statistical data (*Hadley, 1949 Fielding 1957, Colachis & Strohm, 1965*) There is a considerable individual dispersion within the various segments often more than 10° within one segment The reason may be that the intersegmental range of motion depends on the mode in which the movement is performed *Jones (1960)* showed that the range varied if the flexion was begun or ended by drawing in the chin Despite projection and method errors the values indicated for the intersegmental total range of motion however seem to be in comparatively good accordance

Intersegmental measurements of motion on radiographs are extremely inaccurate with respect to other directions except for the sagittal plane This is illustrated by the fact that with two exceptions no numerical data are given *Dittmars (1931)* values were published merely as notes on a sketch *Penning (1968)* stated that the total latero flexion in one direction was 30° , but that it was unevenly distributed over the segments He indicated the rotation at $8-10^{\circ}$ per segment

D Degenerative Changes and Motion

Degenerative changes of the cervical spine begin very early and are primarily localized to the annulus fibrosus in the uncovertebral region The uncinate process is not developed during the first years of life, but begins to grow at the age of 6-9 years and is fully developed at the age of 18 years (*Rathke 1933/34*) Already at 4 years of age (*Hall, 1965*) and at 7 years of age (*Hirsch et al 1967*) fissures in this area were demonstrated and signs of degenerative changes are obvious at the age of 14 years These early changes may be explained by the fact that the disc and the annulus fibrosus are vascular tissues from birth (*Hirsch et al 1967*) As the disc in this area is very thin and the sliding movement in the sagittal plane is large there is a predisposition to fissure formation (*Frykholm 1951*) Changes resembling osteoarthritis are common in the uncovertebral region and according to *Krogdahl & Torgersen (1940)* they may occur without synchronous changes in other parts of the disc

Hirsch Schajowicz & Galante (1967) described the course of disc degeneration in the cervical spine on a series of 111 autopsy specimens The first stage consisted of fissures in the disc surrounded by pronounced vascularized connective tissue Then osteophytes appeared ventrally and

postero laterally. Finally the height of the disc decreased and changes occurred in the cartilaginous endplate and the subchondral bone. Vessels infiltrated the disc which gradually was replaced by connective tissue thus forming a fibrous ankylosis between the vertebral bodies.

The degenerative changes become more severe with increasing age but sometimes grave changes can be observed in young individuals or small changes in old persons (Silberstein 1965). The changes in the disc appear earliest and become most pronounced in the C4-C6 interspaces (Payne & Spillane 1957 Hadley 1956 Ecklin 1960 Silberstein 1960 Hirsch et al 1967) where the range of motion anyhow in the sagittal plane is largest. This has been taken as a sign of mechanical factors causing or accelerating degenerative changes (Hadley 1949 1956).

The degenerative changes in the intervertebral joints follow the classical pattern of osteoarthritis (Hirsch et al 1967). They are most common in the upper and middle portions of the cervical spine (Holt & Yates 1966). There is no correlation between the frequency or the degree of disc degeneration and osteophytes in the first place and secondly of osteoarthritis in the intervertebral joints (Payne & Spillane 1957 Friedenberg et al 1959 Hirsch et al 1967). There is a general consensus of opinions about the total motion of the cervical spine decreasing with age (Blanchard & Kottke 1953 Rossler & Schmeisser 1958 Jones 1960 Zettler & Markuske 1962 Schoening & Hannan 1964) and that increasing degenerative changes in the disc result in a proportionally decreased intersegmental motion (Hadley 1944 Jones 1960 Ball & Meyers 1964 Fielding 1964). On the other hand a locally reduced motion caused by degeneration or post traumatic changes in one segment results in a compensatory increase in the motion of adjacent segments (Jones 1960 Fielding 1964). Consequently disc degeneration must exist in more than one segment to affect the total motion (Schoening & Hannan 1964).

Osteoarthritis of the intervertebral joints could affect the range of motion but Schoening & Hannan (1964) found no correlation between the range of motion and the degree of osteoarthritis or the number of engaged levels. Although the frequency and degree of osteoarthritis are highest in the upper intervertebral joints Jones (1960) also found that the motion is proportionally greater in the upper part of the cervical spine when in high ages changes of the disc in the middle and lower parts caused impairment of mobility.

graphs The table shows that the largest range of motion in the sagittal plane almost regularly was found between C5-C6 This was verified by other authors omitting statistical data (Hadley, 1949, Fielding, 1957, Colachis & Strohm, 1965) There is a considerable individual dispersion within the various segments often more than 10° within one segment The reason may be that the intersegmental range of motion depends on the mode in which the movement is performed Jones (1960) showed that the range varied if the flexion was begun or ended by drawing in the chin Despite projection and method errors the values indicated for the intersegmental total range of motion, however seem to be in comparatively good accordance

Intersegmental measurements of motion on radiographs are extremely inaccurate with respect to other directions except for the sagittal plane This is illustrated by the fact that with two exceptions no numerical data are given Dittmar's (1931) values were published merely as notes on a sketch Penning (1968) stated that the total latero flexion in one direction was 30° but that it was unevenly distributed over the segments He indicated the rotation at $8-10^{\circ}$ per segment

D Degenerative Changes and Motion

Degenerative changes of the cervical spine begin very early and are primarily localized to the annulus fibrosus in the unco vertebral region The uncinate process is not developed during the first years of life but begins to grow at the age of 6-9 years and is fully developed at the age of 18 years (Rathke 1933/34) Already at 4 years of age (Hall 1965) and at 7 years of age (Hirsch et al 1967) fissures in this area were demonstrated and signs of degenerative changes are obvious at the age of 14 years These early changes may be explained by the fact that the disc and the annulus fibrosus are avascular tissues from birth (Hirsch et al 1967) As the disc in this area is very thin and the sliding movement in the sagittal plane is large there is a predisposition to fissure formation (Frykholm 1951) Changes resembling osteoarthritis are common in the unco vertebral region and according to Krogdahl & Torgersen (1940) they may occur without synchronous changes in other parts of the disc

Hirsch Schajowicz & Galante (1967) described the course of disc degeneration in the cervical spine on a series of 111 autopsy specimens The first stage consisted of fissures in the disc surrounded by pronounced vascularized connective tissue Then osteophytes appeared ventrally and

- 2 synchronous recording of γ motion in space of at least 21 points (7 vertebrae each with 3 points)
- 3 the method must not restrict the motion
- 4 reproducible measuring points

Of the measuring methods earlier used on specimens of the spine none fulfilled these demands. The use of steel pins inserted into the vertebrae gives favourable results only if the motion occurs in one plane. Simultaneous measurements of angular changes in several planes requires a large number of protractors fitted to the specimen which may result in restricted motion.

Bartholomew's (1928) method of plaster impressions will cause slackness in the moulds when the specimen has been freed from the soft parts resulting in linear errors in measurement. Methods involving stepped testing of the segments are adverse to the third demand.

Polander's (1966) technique has the advantage of being very accurate but applied to 21 measuring points it would require a considerable number of measuring devices fixed to the specimen which would restrict the motion.

Both functional radiographic examination and cineradiography are disadvantageous inasmuch as a three dimensional course is reduced to a two dimensional representation. The theoretical conditions which would allow the changed positions to be measured quantitatively and with a high geometric quality on radiographs exposed in one plane only are

- a that the motion occurs in one plane which is parallel with the roentgen film or that the angles to the film plane are known
- b that the geometric relations between the focus, object and film are known and
- c that within the object to be measured there are well defined measuring points.

The first demand excludes measurement of *lateral flexion* and rotation in the cervical spine as lateral flexion in a segment cannot occur without synchronous rotation and vice versa. Theoretically the motion in the sagittal plane can be measured if its relation to the film plane is known. At each exposure it is necessary to know where each vertebra to be measured is situated in the film plane—roentgen tube system. For practical reasons this is of course impossible.

As all examinations are based upon points selected in the contour of the vertebral body or the spinal process this means that when measuring a point it must be selected where a roentgen ray is a tangent

OWN INVESTIGATION

A Method

1 *Discussion of Measuring Methods*

Even if the motion, expressed in degrees is large within the cervical spine, the linear motion between the segments is small. Assuming that Penning's (1968) construction of the centre of motion is correct a point at a distance of 20 mm from the centre would change its position only about 0.8 mm which corresponds to an angular motion of 2° . Approximately 20 mm corresponds to the distance from the centre of motion to the anterior border of the superior vertebra. For instance if the total range of motion in a segment is 20° , a linear error in measurement of only 0.8 mm will result in an angular error of 10 per cent.

In order to get a correct idea of both the pattern and the range of motion a method with small linear errors in measurement would be desirable.

The entire cervical spine moves as one unit *in vivo*. With the exception of the upper two interspaces occiput—C1—C2 a segment never moves without a synchronous movement of the adjacent interspace. In order to maintain as normal a condition as possible as well as the normal binding between the vertebrae it seemed advisable to examine the entire cervical spine undivided. This meant that the synchronous motion of six interspaces i.e. seven vertebrae had to be recorded.

Preliminary experiments revealed that a motion cannot be brought about which in the entire cervical spine is limited to one plane. Assuming that each vertebra is a rigid body its position in space can be determined by means of a plane through the vertebra. The position of the plane is determined by three points in the plane which are not in line and which can be reproduced in every position.

In a deliberate direction of motion each vertebra must be able to move freely.

The measuring method should thus cover the following demands

1 *small linear errors in measurement*

- 2 synchronous recording of a motion in space of at least 21 points (7 vertebrae each with 3 points)
- 3 the method must not restrict the motion
- 4 reproducible measuring points

Of the measuring methods earlier used on specimens of the spine none fulfilled these demands. The use of steel pins inserted into the vertebrae gives favourable results only if the motion occurs in one plane. Simultaneous measurements of angular changes in several planes requires a large number of protractors fitted to the specimen which may result in restricted motion.

Verchow's (1928) method of plaster impressions will cause slackness in the moulds when the specimen has been freed from the soft parts resulting in linear errors in measurement. Methods involving stepped testing of the segments are adverse to the third demand.

Rolander's (1966) technique has the advantage of being very accurate but applied to 21 measuring points it would require a considerable number of measuring devices fixed to the specimen which would restrict the motion.

Both functional radiographic examination and cineradiography are disadvantageous inasmuch as a three dimensional course is reduced to a two dimensional representation. The theoretical conditions which would allow the changed positions to be measured quantitatively and with a high geometric quality on radiographs exposed in one plane only are

- a that the motion occurs in one plane which is parallel with the roentgen film or that the angles to the film plane are known
- b that the geometric relations between the focus, object and film are known and
- c that within the object to be measured there are well defined measuring points.

The first demand excludes measurement of latero flexion and rotation in the cervical spine as latero flexion in a segment cannot occur without synchronous rotation and vice versa. Theoretically the motion in the sagittal plane can be measured if its relation to the film plane is known. At each exposure it is necessary to know where each vertebra to be measured is situated in the film plane—roentgen tube system. For practical reason this is of course impossible.

As all examinations are based upon points selected in the contour of the vertebral body or the spinal process this means that when measuring a point it must be selected where a roentgen ray is a tangent

to the vertebral surface. The vertebral body is demarcated by irregular surfaces. If a roentgen ray should be a tangent to a surface in the same point at different exposures, this means that the vertebra always should be in the same position in relation to the film and the focus of the roentgen tube. As the vertebrae move relative to each other, the tangent can strike only one vertebra in the same point while the others have changed their position in relation to the roentgen ray. If a point of measurement the tip of the spinal process is used which in most of the cervical vertebrae is double it is impossible to know which of the tips forms the contour.

This method is, consequently impossible to use for accurate measurements of motion, as the numerous sources of error are uncontrollable.

Bueth Bauml (1954) illustrated this in practice by finding that the sagittal diameter of one and the same vertebra is not always equally long when measuring different roentgen films despite identical technical conditions. Furthermore when studying the published diagrams of motion (Dittmar 1931) and the radiographs (Penning, 1968) it was found that the contour of a vertebra has not the same shape in different positions.

Despite this, the above method seems to be the most favourable, so far, for assessment of the intersegmental range of motion in clinical use as long as the sources of error are borne in mind, and an error of measurement of 2° is not stated at the same time as the range of motion is indicated in tenths of a degree.

The method selected offers a three dimensional radiographic examination at which fixed measuring points have been created by placing small steel balls in each vertebra.

2 Apparatus

On an approximately 2.5 m long stand consisting of an I beam 20 × 20 cm in object table and a roentgen tube are fitted (Fig. 1). The object table (A) is circular and rotatable around a vertical axis which runs through a reference point (R) which is a steel ball with a diameter of 0.8 mm and placed in a pillar of plexiglass. The object table can be locked in seven pre set positions: middle position (pos. 0) at 30°, 22.5° and 15° each way, calculated from the middle position. For this investigation only the positions +22.5° (pos. I) and -22.5° (pos. II) were used. Perpendicular to the rotation plane of the object table there is a roentgen film holder (B) behind the reference point. The holder which is intended for a film size of 24 × 30 cm can be parallelly displaced along an L square ruler (C). The front of the holder consists of a per

Fig 1 The apparatus For description see text

forated surface ground sheet steel and the roentgen film is fixed flat to this by means of partial vacuum (80 mm H₂O) achieved by a suction device

In the object table and in front of the film holder there is a cavity into which a brass cup (E) can be placed and secured

On the stand between the roentgen tube and the object table there is a metal rod (D) through the top of which a bore was made The rod is placed so that a line drawn through the centre of the bore and the centre of the reference point is parallel with the rotation plane of the object table and thus perpendicular to its axis of rotation and to the film plane in position 0

Fig 2 Object table with mounted specimen in position I (2A) and position II (2B)
Views seen from focus of roentgen tube

The roentgen tube is a standard model Siemens Monodor SP 90/3/20 focus 0.6 mm. The attachment of the tube on the stand permits adjustment in all directions and locking in the desired position. Before measurement, the tube is fixed so that the reference point is projected in the centre of the projected bore on the roentgen film. This means that a roentgen beam (interrupted line) from the focus through the reference point strikes the film in position 0 perpendicularly and is at right angles to the axis of rotation of the object table.

When examining the specimen which is fixed to the brass cup, the object table is first turned to position I (Fig. 2A) the film holder is moved to the left and the left part of the film is covered with a roentgen opaque shield and the first exposure can be made. Then the object table is turned to position II (Fig. 2B) the film holder is displaced parallel to the right and the right part of the film is covered ready for the second exposure. Between the exposures the position of the specimen and the position of the film on the holder must not be disturbed.

3 Geometry

The zero point in the primary right angled coordinate system is the reference point (P). The x axis is parallel with the roentgen film and the rotation plane of the object table in a positive direction to the left. The y axis coincides with the rotation axis of the object table in a positive direction upwards. The z axis is consequently at right angles to the film and parallel with the rotation plane of the table and coincides in position 0 with the central beam of the roentgen tube and is positive in the direction towards the focus of the tube. The coordinate system follows the rotation of the table (Fig. 3).

Fig. 3. Rotation of primary coordinate system with the object table. Dashed line runs towards focus of roentgen tube.

Fig 2 Object table with mounted specimen in position I (-A) and position II (-B)
Views seen from focus of roentgen tube

Fig 4 Geometry of the parabolus For description see text

Fig 4 depicts the following geometrical conditions P is a point in the specimen whose x y and z coordinates are searched P is the picture of P on the film in position I (P in position II) R (R' respectively) is the picture of the reference point A is the projection of P in the xz plane and F is the focus of the roentgen tube V is the angle of rotation from position 0

In position I the PBA plane in the pyramid $FPR A'$ is parallel with the base $P R' A'$ Thus the triangle $F A' R$ is uniform with the triangle FAB and the triangle $P R A'$ is uniform with the triangle PBA

$$\frac{FR'}{FB} = \frac{AR}{AB} = \frac{P'A}{PA} \quad (1)$$

The same reasoning is applied to position II and gives

$$\frac{FR}{FB} = \frac{A'R}{AB} = \frac{P A'}{PA} \quad (2)$$

The distances $A'R$ and $A''R$ expressed x and x'' and the distances PA and PA'' expressed y and y'' are measured on the film The distance from the reference point to the film plane is 50 mm (in the formula b mm) and the distance focus—reference point (FR) is 2000 mm (a mm) The angle of torsion, v is 22.5°

By using these values in the formulae (1) and (2) the following equations are obtained

$$\frac{a + \frac{b}{\cos v}}{z} = \frac{x}{x - z \tan v} = \frac{y'}{y} \quad (3)$$

$$\frac{a + \frac{b}{\cos v}}{z} = \frac{x}{x + z \tan v} = \frac{y}{y'} \quad (4)$$

From the formulae it is seen that $y = y''$ If this is not the case the film has been moved on its holder or the specimen has been disturbed when shifting from position I to position II Consequently there is a control when measuring each film

Position I

Position II

Fig. 4 Geometry of the apparatus. For description see text

Fig 4 depicts the following geometrical conditions P is a point in the specimen, whose x , y and z coordinates are searched P is the picture of P on the film in position I (P^* in position II) R (R^* respectively) is the picture of the reference point A is the projection of P in the xz plane and F is the focus of the roentgen tube ι is the angle of rotation from position 0

In position I the $PB'A$ plane in the pyramid $FP'R'A'$ is parallel with the base $PR'A$. Thus, the triangle FAR is uniform with the triangle FAB and the triangle $PARA'$ is uniform with the triangle PBA

$$\frac{FR}{FB} = \frac{AR}{AB} = \frac{PA}{BA} \quad (1)$$

The same reasoning is applied to position II and gives

$$\frac{FR^*}{FB} = \frac{AR^*}{AB^*} = \frac{PA^*}{BA^*} \quad (2)$$

The distances AR' and A^*R^* , expressed x' and x'' and the distances PA' and PA^* expressed y' and y'' are measured on the film. The distance from the reference point to the film plane is 50 mm (in the formula b mm) and the distance focus—reference point (FR) is 2000 mm (a mm). The angle of torsion v is 22.5°

By using these values in the formulae (1) and (2) the following equations are obtained

$$\frac{a + \frac{b}{\cos \iota}}{z} = \frac{x}{x - z \tan \iota} = \frac{y}{y} \quad (3)$$

$$\frac{a + \frac{b}{\cos \iota}}{z} = \frac{x''}{x + z \tan v} = \frac{y}{y} \quad (4)$$

From the formulae it is seen that $y = y$. If this is not the case the film has been moved on its holder or the specimen has been disturbed when shifting from position I to position II. Consequently there is a control when measuring each film

Fig 5 Detail coordinatograph Along an x ruler (1) a metal slide (2) runs to which a y ruler (3) is attached perpendicular to the x ruler Along the y ruler another metal slide runs equipped with an ocular (4) The rulers are graded The metal plates have vernier scales (5) permitting readings of ± 0.00 mm knobs (6) are used for moving the slides The measuring point is adjusted in the ocular ring and the x and y values can be read The arrows indicate directions of motion

4 Measuring on Radiographs

The film is fixed with tape against a flat horizontal glass plate which is transilluminated from below The measurements are performed by the use of a detail coordinatograph (Fig 5) the x ruler of which is placed parallel with the line RR and the values of points R and R' are noted The height adjustment is checked during the entire measuring procedure by ensuring that y and y' are equal in each point After all the points have been measured it is made sure that the instrument has not been displaced laterally by re measuring R and R' Part of the series was measured by the aid of a stereocomparator The instrument used is a monocomparator automatically records the measuring values and produces a punch tape which can be used for data processing In principle the measurements have been made in the same way and the time gained was considerable The distances measured on each film are shown in Fig 6

planes formed by the inserted four measuring points are calculated within each vertebra after each movement. These planes are *ARP* and *ALP* and further *RLA* and *RLP*. If these control angles remain unchanged, this means that the vertebra is not deformed beyond the limits of error of the method. This is also a control that the primary measuring values are not erroneous, for instance by incorrect notes, erroneous punching or mixing of the measuring points.

The cervical vertebrae are often asymmetrical and asymmetrically placed. Thus, the primary measuring points cannot be symmetrically arranged. In order to obtain a symmetrical and comparable neutral position, and to facilitate the study of the motion, four fictive secondary measuring points were assumed in each vertebra at the neutral position (see below). These were selected so that the *A* and *P* points lay in the *xy* plane of the primary coordinate system, and on a line forming the projection in this plane of the line between the primary points *A* and *P*. The secondary measuring point *A* is the projection of the primary measuring point *A* in the *xy* plane, and the distance between the secondary measuring points *A* and *P* was selected to be 40.0 mm. The secondary measuring points *R* and *L* form the end points of a line, 40.0 mm long, the centre point of which divides the *AP* line equally and is parallel with the *z* axis of the primary coordinate system. Thus, the four secondary measuring points form the end points of two 40.0 mm long vectors at right angles to each other, which lie in a plane with the same inclination towards the *xz* plane as the line between the primary *A* and *P* points.

After each movement the position of the secondary measuring points was calculated so that it remained unchanged in relation to the primary measuring points within each vertebra.

As the purpose was to illustrate the intersegmental motion, a secondary coordinate system was placed in each vertebra, using the two described vectors as two of the axes. In this coordinate system the secondary measuring points of the superjacent vertebra were calculated, thus obtaining their motion in relation to the subjacent vertebra (Fig. 7). These stereometric calculations mean a large number of mathematical operations which have been performed by means of data processing.

6 Preparation of Specimen and Testing

According to Hirsch & Galante (1967), Galante (1967) and Tlaczul (1968) the tensile properties of the annulus fibrosus and the longitudinal ligaments change if they are subjected to dehydration. This occurs if

Fig. 1. Mot on a segment of the test animal primary measuring points (A) using secondary measuring points (B) transformed into the secondary coordinate system.

they are not stored in an atmosphere close to a relative humidity of 100 per cent.

In order to protect the specimens in this investigation against dehydration they were always stored in airtight plastic bags. The specimens were always treated at room temperature (approx. 22°C) and very close to 100 per cent RH.

The specimen, consisting of an undivided spine from C2 up to and including Th1 or 3, was freed from musculature and other soft parts only so much that the necessary anatomical details could be identified. All the ligaments, joint capsule, and bone structures were maintained, and as a further protection against dehydration a thin layer of musculature was left.

In each vertebra (C2-Th1) four steel balls (2.08 mm) were inserted. The anterior (I) and the posterior (II) were inserted as closely to the sagittal plane as possible and immediately subcortically in the anterior

planes formed by the inserted four measuring points are calculated within each vertebra after each movement. These planes are *ARP* and *ALP* and further *RLA* and *RLP*. If these control angles remain unchanged, this means that the vertebra is not deformed beyond the limits of error of the method. This is also a control that the primary measuring values are not erroneous for instance by incorrect notes, erroneous punching or mixing of the measuring points.

The cervical vertebrae are often asymmetrical and asymmetrically placed. Thus, the primary measuring points cannot be symmetrically arranged. In order to obtain a symmetrical and comparable neutral position, and to facilitate the study of the motion, four fictive secondary measuring points were assumed in each vertebra at the neutral position (see below). These were selected so that the *A* and *P* points lay in the *xy* plane of the primary coordinate system and on a line forming the projection in this plane of the line between the primary points *A* and *P*. The secondary measuring point *A* is the projection of the primary measuring point *A* in the *xy* plane and the distance between the secondary measuring points *A* and *P* was selected to be 40.0 mm. The secondary measuring points *P* and *L* form the end points of a line 40.0 mm long, the centre point of which divides the *AP* line equally and is parallel with the *z* axis of the primary coordinate system. Thus the four secondary measuring points form the end points of two 40.0 mm long vectors at right angles to each other which lie in a plane with the same inclination towards the *xz* plane, as the line between the primary *A* and *P* points.

After each movement the position of the secondary measuring points was calculated so that it remained unchanged in relation to the primary measuring points within each vertebra.

As the purpose was to illustrate the intersegmental motion, a secondary coordinate system was placed in each vertebra using the two described vectors as two of the axes. In this coordinate system the secondary measuring points of the superjacent vertebra were calculated thus obtaining their motion in relation to the subjacent vertebra (Fig. 7). These stereometric calculations mean a large number of mathematical operations which have been performed by means of data processing.

6 Preparation of Specimen and Testing

According to Hirsch & Galante (1967), Galante (1967) and Tlaczul (1968) the tensile properties of the annulus fibrosus and the longitudinal ligaments change if they are subjected to dehydration. This occurs if

the ball. However, as the focus of the roentgen tube is a surface partial shading of varying dimensions caused a diffuse image of the ball. Thus the centre of the ball did not correspond to the centre of its image. However, a calculation of the discrepancy showed that it did not exceed 0.01 mm within the area to be measured. As the linear measuring results were not indicated with more than one decimal of a millimeter, this error was insignificant.

The geometric formulae (3) and (4) are based on the fact that parts of the apparatus which form the primary coordinate system are at right angles to each other. Within reasonable economical limits this was achieved so that the angular error in no case exceeded one minute of arc. The error of angle of rotation was max $\pm 0.5^\circ$. These minor errors do not affect the first decimal in the result.

The distance focus—reference point (a in the formulae 3 and 4) is 2000 mm (max error ± 2 mm) and the distance between the reference point and the film plane (b in the formulae 3 and 4) is 50 mm (max error ± 0.5 mm).

Primary data. The measuring values x (x) and y (y) are dependent on the dimensional stability of the film and the error in the measuring instrument.

The roentgen film was made of polyester, the coefficient of expansion of which was for the temperature $\text{cm/cm}/^\circ\text{C} = 3.61 \times 10^{-5}$ and for relative humidity $\text{cm/cm}/\% \text{PH} = 1.0 \times 10^{-5}$.

It has not been possible to control these factors. The temperature and relative humidity were recorded, however, and the difference between the exposure and the measuring never exceeded 4°C and 40% PH. The longest distance measured on any of the films was 280 mm. The linear error of measurement depending on the dimensional instability of the film was calculated to be maximum ± 0.1 mm under the most unfavourable conditions.

The measuring error of the detail coordinatograph was max ± 0.05 mm.

In order to get an idea as to the importance of these sources of error and the mathematical procedure from the practical point of view a plastic model was made with 28 inserted stainless steel balls. The model was radiographed and the primary data treated according to the same system as used for the specimens.

Eight exposures were performed with the model placed in various positions in front of the film. From the coordinates of the 28 primary measuring points 14 distances were derived, the true lengths of which

surface of the vertebral body and the spinal process respectively. The two lateral balls (*R* and *L*) were inserted in the cranial intervertebral joint processes.

In the longitudinal axis of the dens epistrophei, a screw was inserted the shaft of which resembles a hook. Through the vertebral body of C2 immediately below the cranial intervertebral joint surface a transversal bore was drilled through which a Kirschner wire could be inserted.

The two bottom vertebrae of the specimen were fixed in the brass cup (Fig 1 E) with Plastic Padding—unsaturated polyester resin—(Hirsch 1964) which was inserted into the cavity of the object table. One frontal and one lateral view were exposed in order to check the positions of the indicator balls. Then the cup was fixed so that the sagittal plane of the specimen would coincide as closely as possible with the *xy* plane of the primary coordinate system. The specimen was now in a resting position and was not affected by any loading. One view, the neutral position, was exposed according to the earlier description.

By means of thin metal wires attached to the screw in the top of the specimen and adjustably fixed to lever arms in the periphery of the object table the specimen was drawn backwards into extreme extension. From this point the entire motion was performed into extreme flexion in ten steps. One exposure was made between each step. The motion was then reversed in the same way. Consequently the motion in the sagittal plane was divided into 19 steps.

The base of the specimen was rotated 90° and latero flexion was performed from the extreme left to the extreme right and back in 13 steps. In the transverse bore in C2 a Kirschner wire was inserted and via a clamp which allowed free play up and down the specimen was rotated vertically. The rotation was performed from extreme left to extreme right in seven steps.

A total of 40 radiographs were thus obtained each having 58 measurable points i.e. 2300 points per specimen.

7 Discussion of Method

The following sources of error exist

The apparatus. The projection of each ball strikes the film at an oblique angle which means that the view of the ball will be elliptic. If the source of radiation were a point the view of the ball would be sharply demarcated and its centre would correspond to the centre of

the ball. However, as the focus of the roentgen tube is a surface, partial shading of varying dimensions caused a diffuse image of the ball. Thus the centre of the ball did not correspond to the centre of its image. However, a calculation of the discrepancy showed that it did not exceed 0.01 mm within the area to be measured. As the linear measuring results were not indicated with more than one decimal of a millimeter, this error was insignificant.

The geometric formulae (3) and (4) are based on the fact that parts of the apparatus which form the primary coordinate system are at right angles to each other. Within reasonable economical limits, this was achieved so that the angular error in no case exceeded one minute of arc. The error of angle of rotation was $\max \pm 0.5^\circ$. These minor errors do not affect the first decimal in the result.

The distance focus—reference point (a in the formulae 3 and 4) is 1000 mm (max error ± 2 mm) and the distance between the reference point and the film plane (b in the formulae 3 and 4) is 50 mm (max error ± 0.5 mm).

Primary data. The measuring values x , x' and y (y') are dependent on the dimensional stability of the film and the error in the measuring instrument.

The roentgen film was made of polyester, the coefficient of expansion of which was for the temperature $cm/cm/^\circ C = 3.61 \times 10^{-5}$ and for relative humidity $cm/cm/\% RH = 1.0 \times 10^{-5}$.

It has not been possible to control these factors. The temperature and relative humidity were recorded, however, and the difference between the exposure and the measuring never exceeded 4°C and 40% RH. The longest distance measured on any of the films was 80 mm. The linear error of measurement, depending on the dimensional instability of the film, was calculated to be maximum ± 0.1 mm under the most unfavourable conditions.

The measuring error of the detail cinematograph was $\max \pm 0.1$ mm.

In order to get an idea as to the importance of these sources of error and the mathematical procedure, from the practical point of view, a Plexiglas model was made with 28 inserted stainless steel balls. The model was radiographed and the primary data treated according to the same system as used for the specimens.

Eight exposures were performed with the model placed in various positions in front of the film. From the coordinates of the 28 primary measuring points, 14 distances were derived, the true lengths of which

were unknown. Of the eight values obtained for each distance a calculation was made for the mean, the standard error of the mean (s.e.m.) and the standard deviation (S.D.). Of the 14 values obtained of s.e.m. and S.D. a calculation was made for the mean and S.D. (Table 2).

Table 2

	N	Mean	S.e.m.	S.D.
Standard deviation	14	0.093	0.000	0.036

If the variations in S.D. are used to find the reproducibility of the length determinations, the mean reproducibility will be 0.08. This means that the error of the measuring method with respect to the apparatus and the two primary geometrical formulae was less than 1/10 mm. The mean of the distances measured was 47.2 mm which gave a standard deviation of 0.2 per cent of the mean distance.

The same 14 distances were calculated on the coordinates of the same points in the secondary coordinate system. According to the definition all these distances should be 40.0 mm. The mean of the 112 distances was 39.98 mm (s.e.m. 0.1 mm, S.D. 0.9 mm). The deviation from 40.0 mm was not significant. The standard deviation of the whole procedure including all the geometrical calculations was thus 0.9 mm or 2.25 per cent of the defined distance.

B. Material

1. Selection and Age Distribution

The investigation included 28 cervical spines which were obtained from the Departments of Pathology, University City Hospital, Gothenburg.

The specimens were removed with surrounding musculature and immediately placed in plastic bags. If the examination could not be performed at once the specimen was stored in a deep freeze refrigerator at -25°C but were thawed to room temperature before testing.

The specimens were selected to a certain extent. Specimens from patients who had died in malignant diseases were avoided. Furthermore all the specimens were rejected which on preparation or radiographic examination showed signs of other changes than degenerative. This meant that cervical spines with post-traumatic changes of the type luxations or subluxations were excluded.

Much care was taken to avoid damaging the bone structures joint capsules or ligaments when collecting or preparing the specimens. If any lesion of this type was revealed the specimen was rejected.

Age sex and cause of death are tabulated (Table 3). The age of the deceased ranged from 11 to 67 years (mean age 52.0 years). Half of the series belonged to the age group 40-60 years.

2. Classification of Degenerative Changes

In order to correlate the variation in the pattern and the range of motion to degenerative changes roentgenographic and microscopic assessments were made.

Table 3

Spec N	Age years	Sex	Cause of Death
1	11	F	Cerebral ischemia
	10	M	Bronchopneumonia

Fig 8 Sketch showing how the specimens were cut (Hirsch *et al* 1967 Repr with permission of authors)

The roentgenological changes were studied on the frontal and lateral views and on oblique views on which the specimen had been rotated 22.5° in either direction from the frontal view. The two latter projections gave a good view of the intervertebral joints.

Table 4 Grading of Degenerative Changes

Grade	Disc	Intervertebral Joint
Macroscopic changes		
0	Normal disc. Shiny white annulus and nucleus. Distinct border between annulus and nucleus	Normal cartilage shiny smooth white
1	Laminated fibrous structure of annulus	Rough dry surface with small erosions
2	Obvious degenerative changes in nucleus and annulus fissures	Pronounced erosion
3	Marked degeneration in both annulus and nucleus. Ruptures and lacunations up to complete replacement of the nucleus by fibrous tissue	Total destruction of cartilage
Roentgen graphic changes		
0	Normal height. No osteophytes	Normal joint space no osteophytes
1	Slight reduction of disc level. Minimal to small osteophytes. Irregular reduction of disc level. Moderate osteophytes. Slight subchondral sclerosis	Slightly reduced joint space. Small osteophytes. Reduced joint space. Moderate osteophytes and irregular cartilage bone hardening
3	Irreversible total reduction of disc level. Large osteophyte	Large osteophytes to roentgenologic ankylosis

For the macroscopic evaluation the specimens were cut according to the principles stated by *Hirsch et al* (1967). An approximately 4 mm thick slab was cut from the sagittal plane of the entire specimen (Fig 8.1). One of the halves was cut in the horizontal plane of each disc (Fig 8.3) and the other vertically through the uncus region (Fig 8.2). Each disc thus was divided so that a cross section through one half, a section of its sagittal extension and an oblique section through the other half were obtained. The cuts of the two specimen halves passed through the intervertebral joints on either side which could easily be opened allowing the joint cartilage to be examined.

The macroscopic assessment was concentrated on the condition of the disc and the joint cartilage and the roentgenologic on the adjacent bone structure.

The condition of the disc was evaluated according to statements on lumbar discs made by *Friberg & Hirsch* (1949-50) and *Hirsch & Schajowicz* (1955).

Fig 9 Distribution of degenerative changes

The limits between the various degrees as illustrated in Table 4 are indistinct but the purpose was not to give a detailed description of the degenerative changes but instead to obtain a relative grading.

According to the table each disc and each intervertebral joint can receive 0-6 points. To prevent the degenerative changes of the intervertebral joints from being exaggerated in relation to the disc the total of the two joints of each interspace was divided by two. By adding the points of the disc and the joints each interspace may receive 0-12 points. The distribution of the degenerative changes on various segments is given in Fig 9.

The figure shows that in the C5/6 interspace most of the degenerative changes were found and that they decreased gradually with the distance from that interspace.

In order to check that the series similar to earlier investigations showed increasing degeneration with increasing ages (Silberstein 1967, Hirsch *et al* 1967) and that the grading and the evaluation were correct a *T* test was performed. The specimens were divided into two groups.

each including 14 one with ages ranging from 11-53 years the other from 55-67 years. The degree of degeneration was compared in each interspace and in the entire specimen. The latter age group revealed at the 1% level significantly increasing degenerative changes in all the interspaces and in the entire specimen.

Fig. 9 Distribution of degenerative changes

The limits between the various degrees as illustrated in Table 4 are indistinct but the purpose was not to give a detailed description of the degenerative changes but instead to obtain a relative grading.

According to the table each disc and each intervertebral joint can receive 0-6 points. To prevent the degenerative changes of the intervertebral joints from being exaggerated in relation to the disc the total of the two joints of each interspace was divided by two. By adding the points of the disc and the joints each interspace may receive 0-12 points. The distribution of the degenerative changes on various segments is given in Fig. 9.

The figure shows that in the C5/6 interspace most of the degenerative changes were found and that they decreased gradually with the distance from that interspace.

In order to check that the series similar to earlier investigations showed increasing degeneration with increasing ages (Silberstein 1963, Hirsch et al 1967) and that the grading and the evaluation were correct a *T* test was performed. The specimens were divided into two groups.

Fig. 10 Course of motion of measuring point on vertebra on an infl. contrasted in the x/y plane (top) and in the x/z plane (bottom). Solid line indicates extreme flexion, dashed line indicates extreme extension, and dotted line neutral position.

(Fig. 11) Two diagrams were obtained of the latero flexion: one for the motion from the extreme right to the extreme left side and one for the reverse motion.

All the ranges of motion were indicated in angles and in relation to the neutral position of each vertebra. For calculation of the angles the coordinates were used for the extreme positions of the measuring points. At motion in the sagittal plane the A and I points were projected in the sagittal plane of the vertebra. At latero flexion the I and J points were projected in the frontal plane (Fig. 12A) and at rotation in the horizontal

RESULTS

A General Remarks

The results are based on approximately 100 000 primary measuring values, which after data processing resulted in x , y and z coordinates for approximately 35 000 measuring points and the earlier described control angles

These angles are calculated in all exposures and for the same vertebra only within a few tenths of a degree. Singular deviations above this limit are very large and obviously depend on error when measuring the radiograph or when punching the results. When a large deviation was found the result of this exposure was rejected. If any vertebra was deformed under load it seems reasonable to believe that the deformation is largest in the position where the specimen was subjected to the heaviest force i.e. in the extreme positions of the movements. As a control the angles in the neutral position and in the eight extreme positions were chosen in seven random selected specimens. In each vertebra the mean, the s.e.m. and the S.D. for these nine pairs of angles were calculated. Of the 98 values obtained for the s.e.m. and the S.D. the mean, the s.e.m. and the S.D. were calculated and compared with the values obtained in the same way for all the control angles of the Plexiglas model. The differences are not statistically significant and therefore it can be assumed that the vertebrae were not deformed outside the error of the method. Thus in the following they can be regarded as rigid bodies.

The secondary coordinate system was drawn on transparent paper. The measuring points were inserted and their stepwise movements were indicated. In this way a diagram of motion was obtained.

The motion in the sagittal plane was plotted in the xy plane (lateral view of the vertebra) and the xz plane (the vertebra seen from above) of the secondary coordinate system (Fig. 10). Two diagrams were obtained, one for the motion from extreme extension to extreme flexion and one for the reverse motion.

The latero flexion and the rotation were plotted in the yz plane (front view of the vertebra) and the xz plane of the coordinate system.

Fig 10 Course of motion of measuring points in extension and flexion trace I in the x/y plane (top) and the x/z plane. Point dashed line indicates extreme flexion dashed line indicates extreme extension solid line neutral position

(Fig 11) Two diagrams were obtained of the latero flexion one for the motion from the extreme right to the extreme left side and one for the reverse motion

All the ranges of motion were indicated in angles and in relation to the neutral position of each vertebra. For calculation of the angles the coordinates were used for the extreme positions of the measuring points. At motion in the sagittal plane the A and P points were projected in the sagittal plane of the vertebra. At latero flexion the R and L points were projected in the frontal plane (Fig 12A) and at rotation in the horizontal

RESULTS

A General Remarks

The results are based on approximately 100 000 primary measuring values which after data processing resulted in x y and z coordinates for approximately 35 000 measuring points and the earlier described control angles

These angles are calculated in all exposures and for the same vertebra vary only within a few tenths of a degree. Singular deviations above this limit are very large and obviously depend on error when measuring the radiograph or when punching the results. When a large deviation was found, the result of this exposure was rejected. If any vertebra was deformed under load it seems reasonable to believe that the deformation is largest in the position where the specimen was subjected to the heaviest force, i.e. in the extreme positions of the movements. As a control the angles in the neutral position and in the eight extreme positions were chosen in seven random selected specimens. In each vertebra the mean the s.e.m. and the S.D. for these nine pairs of angles were calculated. Of the 98 values obtained for the s.e.m. and the S.D. the mean the s.e.m. and the S.D. were calculated and compared with the values obtained in the same way for all the control angles of the Plexiglass model. The differences are not statistically significant and therefore it can be assumed that the vertebrae were not deformed outside the error of the method. Thus in the following they can be regarded as rigid bodies.

The secondary coordinate system was drawn on transparent paper. The measuring points were inserted and their stepwise movements were indicated. In this way a diagram of motion was obtained.

The motion in the sagittal plane was plotted in the xy plane (lateral view of the vertebra) and the xz plane (the vertebra seen from above) of the secondary coordinate system (Fig. 10). Two diagrams were obtained, one for the motion from extreme extension to extreme flexion and one for the reverse motion.

The latero flexion and the rotation were plotted in the y -plane (front view of the vertebra) and the xz plane of the coordinate system.

Fig 11 Course of motion of measuring points in latero flexion and rotation traced in y plane (top) and x plane. Interruption in the courses indicates neutral position. Arrows indicate direction of motion from left to right latero flexion.

plane (Fig 12B). Thus the range of motion is expressed in the angle formed by the neutral position of the sagittal and the frontal axes respectively, and the projection in each plane of the same axis after motion.

B Pattern of Motion

1 Sagittal Plane

The two diagrams obtained from each vertebra of the motion in the sagittal plane were compared to each other. In no case of the entire series did these two diagrams of motion reveal different patterns which

Fig 13 T1 pattern of motion in the sagittal plane From above extension neutral position and flexion. Bottom motion projected in sagittal and horizontal planes

Fig 12 B P and L projected in horizontal plane and the calculated rotation angle ν

respective positions of two random selected points in two phases of the motion. The principle was used for each step of the motion in the sagittal plane (Fig 14). The intersections will form a straight line, regularly situated within the subjacent vertebral body. In motion from extension to flexion the axis moves from below posteriorly upwards anteriorly thus towards the concave side of the motion.

However a detailed study of the diagrams shows that the courses of motion usually are rectilinear but sometimes arched with the convexity towards or away from the vertebra. It has been impossible to determine whether the axis of motion is fixed or moves.

The distance of the axis from the vertebra decides the course of the motion. The closer the centre of motion is to the vertebra the less the translation per degree of rotation thus the steeper the course.

In order to obtain a relative measure of this the so called Top angle

Fig. 1a Construction of T angle A_E-A_F and P_E-P_F are the courses of motion of the interior and posterior or nearing joint. A small T angle indicates a steep course of motion (top) and a large T angle indicates a flat course (bottom)

P	0 0	0 01	0 001		

Fig 14 Centre of motion if courses of measuring points are arched (dash at C) or if they are rectilinear (line at C) Subjacent vertebral body indicated in grey

(T angle) was constructed in each vertebra as follows (Fig 15) The courses of motion of the anterior and posterior measuring points were extended in a cranial direction and the angle formed was calculated The larger the angle is the more extensive the sliding of the vertebra will be in relation to its tilt If the T angle is 180° there is no tilt if the T angle is 0° there is no sliding The mean of the T angles in the various interspaces were compared in pairs in the whole series (Table 5)

The T angle of C2 is significantly larger than that of all the other vertebrae and of C6 significantly less than that of all the others with the exception of C7 Furthermore the T angles of C3 and C4 are larger than the angle of C7

Thus the course of motion is the most flat in C2 C6 takes the steepest and C7 the next steepest course while the courses of the remaining vertebrae are uniform This means that the axis of motion of C2 is situated furthest distal to the vertebra and the axes of C6 and C7 lie closest to their respective vertebra

C7	-2.2690*	-2.1480*

2P=0.05* Only significant differences shown

The ratio extension/flexion varies with each interspace (Table 6). The degree of flexion is always higher than that of extension, and the difference is most pronounced in the upper portion of the cervical spine. The flexion is almost double as compared to extension in C2, while C6 and C7 reveal the relation 4:5. The individual variation, however, is very large and the differences are significant at the 5% level only when C2 and C4 are compared with C6 and C7.

The effect of degenerative changes on the pattern of motion was examined by studying the variations in the T angle and the ratio extension/flexion.

Within each interspace the values were arranged according to the increasing degree of degeneration and the least degenerated half was compared with the most degenerated.

On all levels the T angle becomes reduced with increasing degeneration. Thus the course of motion will be steeper with increasing degeneration. The T test (Table 7) is not significant for any singular vertebra but as they were all reduced there is still a statistical significance at the 5% level (Sign test).

The ratio extension/flexion does not alter significantly except for C5, where with increasing degeneration the flexion becomes reduced in relation to the extension (Table 8).

2 Frontal and Horizontal Planes

The pattern of motion in these two planes are dealt with simultaneously as they are very uniform.

The two diagrams of the pattern of motion in the frontal plane were compared to each other and in no case was there any difference in the pattern when the motion occurred from the right to the left as compared to the reverse direction.

The motion in the frontal plane (Fig 16) is a combination of lateral tilt and rotation in the same direction i.e. latero flexion to the right is combined with rotation to the right (clockwise) and latero flexion to

Fig 16 The pattern of motion in the frontal and horizontal planes From above latero flexion and rotation to the right neutral position and latero flexion and rotation to the left Bottom Motion projected in frontal and horizontal planes

the left is combined with rotation to the left (anticlockwise) The pattern of motion in the horizontal plane is the same as in the frontal plane

The centre of motion in both planes is situated in the sagittal plane and in the anterior contour of the vertebral body This was proved due to the position there of the anterior measuring point In fact on the diagrams of motion it is found that the anterior measuring point regularly is unmoved or has moved within a very limited space The distance covered by the A point from one extreme position to the other in latero flexion and in rotation was calculated for all the vertebrae The mean was 0.88 mm (s.e.m. 0.04 S.D. 0.42) Thus the distance is very small and the anterior measuring point lies very closely to the centre of motion It was also found that the other measuring points described arched courses with their concavity directed towards the A point

The proportion between latero flexion and rotation when the specimen was latero flexed was obtained by dividing the latero flexion by rotation expressed in degrees The ratio obtained was compared in pairs (Table 9)

The rotation combined with latero flexion was proportionally largest for C2 where the ratio was 3.2 and gradually diminished downwards in the cervical spine In C7 the latero flexion was 7.5 times larger than the rotation occurring at the same time The difference is always statistically significant when a vertebra is compared with the vertebra two steps below

The ratio rotation/latero flexion when rotating the specimen was compared in the same way (Table 10)

The latero flexion combined with rotation was largest for C2 and least for C7. A comparison between the other vertebrae was not statistically significant.

The effect of the degenerative changes on the pattern of motion in the frontal and horizontal planes were studied by comparing the least degenerated half of the series with the most degenerated. Neither the distance of motion from one extreme position to the other covered by the A point nor the ratio latero flexion/rotation or rotation/latero flexion revealed any statistically significant differences in any interspace.

C Range of Motion

The values reported refer to the entire series and it must be borne in mind that the series includes various degrees of degeneration. The ranges of motion cannot be regarded as mean values of spines with non-degenerated unaffected discs.

The values of latero flexion and rotation are the total of the range to the right and to the left.

1 Sagittal Plane

The mean of the total range of motion in the sagittal plane in this series was

Extension 24 (sem 1 SD 6)

Flexion 40 (sem 2 SD 8)

Total 64 (sem 2 SD 10)

There were large individual variations

The distribution of the total range of motion within the cervical spine varied (Table 11) The range of motion was least in C2 and increased in C7 and C3 in the order mentioned The middle cervical vertebrae C4 C5 and C6 had the most equal and the largest range of motion

A comparison of the range of motion in each interspace between the most degenerated and the least degenerated half of the series did not reveal any statistically significant differences at any level neither in extension flexion nor total motion In order to control this result the series was divided into several small groups with regard to the degree of degeneration and a variance analysis was performed There were no criteria of the degree of degeneration having any effect on the range of motion

2 Frontal Plane

There was no difference in this series between the range of motion to the right and to the left

As the intersegmental range of motion when the specimen was latero flexed, was related to the neutral position of each vertebra it was not geometrically correct to add together the intersegmental ranges of motion in order to obtain the total range. As the deviation was small the addition was still made and the mean values obtained

Latero flexion 49° (s e m 3° S D 14°)

Combined rotation 28° (s e m 2° S D 8°)

There were large individual variations

The intersegmental range of motion had a comparatively even distribution with the exception of C7 which moved less than the others (Table 12). The rotation combined with latero flexion was unevenly distributed in the cervical spine (Table 13). The proportional relation has been indicated in Table 9 (Page 49)

There were no statistically significant differences when the intersegmental range of motion in the least degenerated half of the series was compared with the most degenerated

3 Horizontal Plane

The total range of motion when the specimen was rotated was calculated in the same way as when it was latero flexed and the mean values were

Rotation 45° (s e m 5° S D 18°)

Combined latero flexion 24° (s e m 3° S D 10°)

Also in this plane the individual variation was very large. The intersegmental distribution revealed that the range of motion was largest in C4 and least in C2, C6 and C7 (Table 14)

The mean of the latero flexion combined with rotation was largest in C3 and least in C7 (Table 15). The ratio has been indicated in Table 10 (Page 50)

No statistically significant differences could be demonstrated in this plane of motion either in a comparison between less or more degenerated interspaces

D Conclusions and Discussion

1 Pattern of Motion

The patterns of motion in the cervical spine are of two entirely different types. In the sagittal plane the motion is limited to one plane, i.e. each point in a vertebra moves parallel to the sagittal plane. The motion can be described as a rotation in this plane around an immobile or mobile axis which is perpendicular to the plane.

In the frontal and the horizontal planes the motion, on the other hand, occurs in several planes, but is symmetrical in relation to the sagittal plane and therefore, can be described as a rotation around a point in this plane.

These two types of motion are controlled by the shape of the discs and the intervertebral joints. As the system of an ideal case is symmetrical with respect to the sagittal plane, but asymmetrical with respect to the other two planes it is reasonable to expect different patterns of motion. In principle the patterns of motion observed do not differ from those reported by other authors (cf. Review of Literature).

The axis of motion in the sagittal plane was found to lie in the subjacent vertebral body, however, on different levels in different segments. The size of the Top angle (Page 34) shows that the axis of the C 2 motion lies further distal than those of C 6 and C 7. This finding is in accordance with Penning's (1968) positioning of the C 2 axis of motion caudal in the C 3 vertebral body and the C 6 axis caudal in the C 7 vertebral body. It has been impossible to decide whether the axis of motion is immobile or whether it moves.

The centre of motion in the frontal and horizontal planes proved to lie in the anterior contour of the vertebra and in the sagittal plane. The diminutive movement less than one millimeter made by the anterior measuring ball at motion from one extreme position to the other for obvious reasons depends on the impossibility of placing the ball right in the centre of motion.

The position of this centre has not been mentioned in earlier literature. *Balle* (1931) however observed that a vertebra in latero flexion slides on the subjacent vertebra towards the convex side. This is in good accordance with a centre of motion placed anteriorly to the joint processes the latter of which at rotation are turned forwards on the convex side and on a frontal view are projected further lateral than the processes of the subjacent vertebra.

As mentioned earlier the Top angle is a measure of the shape of the course of motion in the sagittal plane. The proportion between latero flexion and rotation when the specimen is latero flexed is a measure of the shape of the course of motion in the frontal and horizontal planes. If latero flexion occurs without simultaneous rotation the motion is limited to one plane and the ratio is infinite (latero flexion

\propto rotation $0 \quad \frac{\lambda}{0} = \text{infinity}$). If the latero flexion and the rotation are equal there will be equal motion in both planes and the ratio will be 1. The same reasoning can be applied to the ratio rotation/latero flexion when the specimen is rotated.

C2 has the largest Top angle and at the same time the lowest ratio of latero flexion/rotation and rotation/latero flexion. This means that C2 at the same time has the most flat course of motion in the sagittal plane, the largest rotation combined with latero flexion and the largest latero flexion combined with rotation. There is a complete reverse condition for C7.

The tendency for the vertebrae lying in between even if it is not statistically significant in all details is that the T angle becomes reduced and the two ratios increase gradually down the cervical spine.

The above statement can be regarded as a proof that the freedom of motion found in a vertebra is related to the subjacent one, is largest in the upper portion of the cervical spine and becomes reduced in a distal direction. It was also found that the flexion proportionally was the largest in C2 and became reduced in a distal direction.

Degenerative changes affect the pattern of motion only with respect to the course in the sagittal plane and the proportion between extension and flexion in the interspace of C5/6.

The course of motion is statistically significant steeper with increasing degeneration and in analogy with the above statements this implies that the freedom of motion of the vertebrae in relation to the subjacent one becomes reduced with increasing degeneration.

The fact that the flexion was reduced in relation to the extension

only in C5 may depend on the most pronounced changes in the series being found there

2 Range of Motion

There were large individual variations in all directions of the range of motion in the cervical spine

The means of the intersegmental range of motion in the sagittal plane and at latero flexion lie within the limits found on earlier studies of specimens but at rotation the mean is lower

In the sagittal and the horizontal planes, the intersegmental range of motion is largest in the middle parts of the cervical spine, while the motion in the frontal plane is more evenly distributed

Contrary to most of the earlier investigations there is no correlation between reducing range of motion and increasing degeneration This applies to all directions of motion, to all interspaces and also to the total motion of the specimens

Galante (1967) stated regarding the annulus fibrosis in the lumbar spine that after the middle of the third decade no significant changes in tensile properties were present as a function of aging

It is true that *Galante's* results deal with the lumbar spine, but if his findings can be applied to the cervical spine this may partly explain why the range of motion is not affected by degenerative changes in the present series in which all specimens except two were obtained from deceased persons older than 30 years

Furthermore *Hirsch & Levin* (1968) when studying the range of motion in the lumbo sacral synovial joints found that disc degeneration did not affect the excursion of the L5 facet relative to the sacrum

However, it is not sure that changes in the morphology of the disc and the intervertebral joints cause a reduction of the range of motion *Schoening & Hannan* (1964) measured the total range of motion of the cervical spine in living subjects by means of a 17" wand firmly fixed to the occiput Even if the method has large sources of error there was no correlation between the range of motion in the first place and interspace narrowing in one level posterior bar or apophyseal arthritis on one or many levels in the second place Contrary to this pain in the neck, arms and upper trunk tenderness over the articular masses and spinal processes pain with passive neck motion or increased muscularity caused reduced range of motion

SUMMARY

The primary intention was to demonstrate the intersegmental pattern of motion in the cervical spine and therefore an apparatus for three dimensional radiographic examination of autopsy specimens was designed

The series consisted of 28 autopsy specimens including C3-Th1 in the age groups 11-67 years. The specimens were indicated with steel balls and tested for the pattern of motion in the sagittal frontal and horizontal planes. The motion in each plane was represented by a number of stepped movements.

After data processing including a number of geometrical transformations motion diagrams were drawn.

The motion in extension flexion was parallel to the sagittal plane and made its course around an axis in the subjacent vertebral body perpendicular to this plane. The appearance of the course varied between the different interspaces. Increasing degenerative changes affected the pattern of motion in the sagittal plane so that the freedom of motion between the vertebrae was reduced.

The patterns of motion in latero flexion and rotation were similar to each other. One movement is always combined with the other and there is only a difference in the proportion between latero flexion and rotation when the specimen is latero flexed or rotated. The centre of motion is a point situated in the anterior contour of the body of the moving vertebra and in the sagittal plane. The pattern of motion in the frontal and horizontal planes were not affected by degenerative changes.

The maximum ranges of motion in all planes were calculated and the results lay within the limits earlier found on examinations of specimens except for the rotation which in this series was lower.

Degenerative changes had no effect on the range of motion in any planes or in any interspaces.

only in C5 may depend on the most pronounced changes in the series being found there

2 *Range of Motion*

There were large individual variations in all directions of the range of motion in the cervical spine

The means of the intersegmental range of motion in the sagittal plane and at latero flexion lie within the limits found on earlier studies of specimens but at rotation the mean is lower

In the sagittal and the horizontal planes the intersegmental range of motion is largest in the middle parts of the cervical spine while the motion in the frontal plane is more evenly distributed

Contrary to most of the earlier investigations there is no correlation between reducing range of motion and increasing degeneration. This applies to all directions of motion to all interspaces and also to the total motion of the specimens

Galante (1967) stated regarding the annulus fibrosis in the lumbar spine that "after the middle of the third decade no significant changes in tensile properties were present as a function of aging"

It is true that *Galante's* results deal with the lumbar spine but if his findings can be applied to the cervical spine this may partly explain why the range of motion is not affected by degenerative changes in the present series in which all specimens except two were obtained from deceased persons older than 30 years

Furthermore *Hirsch & Lewin* (1968) when studying the range of motion in the lumbo sacral synovial joints found that disc degeneration did not affect the excursion of the L5 facet relative to the sacrum

However, it is not sure that changes in the morphology of the disc and the intervertebral joints cause a reduction of the range of motion. *Schoening & Hannan* (1964) measured the total range of motion of the cervical spine in living subjects by means of a 17" wand firmly fixed to the occiput. Even if the method has large sources of error there was no correlation between the range of motion in the first place and inter space narrowing in one level posterior bar or apophyseal arthritis on one or many levels in the second place. Contrary to this pain in the neck, arms and upper trunk, tenderness over the articular masses and spinal processes, pain with passive neck motion or increased muscularity caused reduced range of motion

INTRODUCTION

The growth of man hardly seems to have been a subject of study before the eighteenth century. Up to that time it had been the object of philosophical, religious and poetical reflections. Aristotle's natural philosophy considers growth to be one of the three co-operating primary forces in the living organism but concrete observations of the growth of individuals do not appear to have been preserved nor probably made to judge from the loose speculations and system constructions supplied by for instance Galen. So worthy a representative of natural science of the Renaissance as *Fernel* (1548) has — despite rising opposition to Aristotle — hardly anything to add to the then existing knowledge of growth.

The oldest preserved systematic record of growth dates to 1759—1777 when Count *Gueneau de Montbeillard* carefully recorded every six months the increase in the height of his son. A few decades earlier 1727 however the English biologist *Stephen Hales* had carried out the oldest known animal experiment on skeletal growth by boring holes in chicken bones. Here he was able to show that the growth of the long bones takes place at the epiphyses and not interstitially. The result was confirmed by another method by *Duhamel* (1742–1743). The surgeon *J. Hunter* at the end of the eighteenth century and the physiologist *Flourens* at the mid nineteenth century carried out related investigations.

Towards the end of the nineteenth century a rapidly increasing number of investigations by anatomists and physiologists into the morphology and physiology of bone tissue were made wherein the skeletal growth was given increased consideration. Because the growth of the individual and the skeleton from a mathematical standpoint can be regarded as a special example of the velocity concept (length increase/time unit) two deviations from the regular norm were encountered at a closer study of it: acceleration and retardation. Already *Montbeillard's* growth diagram had proved that both these variants occur during a child's normal development. Apart from this it has always been known that the growth process can be slowed or can stop for a variety of causes (dwarfism, shortening of the extremities after polio &c.) although the causal connexion has been obscure. That many factors on the other hand can induce growth acceleration has seemed improbable. It could only be demonstrated by more thorough scientific investigation of growing individuals.

INTRODUCTION

The growth of man hardly seems to have been a subject of study before the eighteenth century. Up to that time it had been the object of philosophical, religious, and poetical reflections. Aristotle's natural philosophy considers growth to be one of the three co-operating primary forces in the living organism, but concrete observations of the growth of individuals do not appear to have been preserved, nor probably made, to judge from the loose speculations and system constructions supplied by, for instance, Galen. So worthy a representative of natural science of the Renaissance as *Fernel* (1548) has — despite rising opposition to Aristotle — hardly anything to add to the then existing knowledge of growth.

The oldest preserved systematic record of growth dates to 1759–1777 when Count *Gueneau de Montbeillard* carefully recorded every six months the increase in the height of his son. A few decades earlier, 1727, however, the English biologist *Stephen Hales* had carried out the oldest known animal experiment on skeletal growth by boring hole in chicken bones. Here he was able to show that the growth of the long bones takes place at the epiphyses and not interstitially. The result was confirmed by another method by *Duhamel* (1742–1743). The surgeon *J. Hunter* at the end of the eighteenth century and the physiologist *Flourens* at the mid nineteenth century carried out related investigations.

Towards the end of the nineteenth century a rapidly increasing number of investigations by anatomists and physiologists into the morphology and physiology of bone tissue were made, wherein the skeletal growth was given increased consideration. Because the growth of the individual and the skeleton from a mathematical standpoint can be regarded as a special example of the velocity concept (length increase/time unit) two deviations from the regular norm were encountered at a closer study of it: acceleration and retardation. Already *Montbeillard's* growth diagram had proved that both these variants occur during a child's normal development. Apart from this it has always been known that the growth process can be slowed or can stop for a variety of causes (dwarfism, shortening of the extremities after polio, &c.) although the causal connexion has been obscure. That many factors on the other hand can induce growth acceleration has seemed improbable; it could only be demonstrated by more thorough scientific investigation of growing individuals.

During the latter half of the nineteenth century, however, several scientists found that fracture in a long bone in a growing person could apparently induce a growth stimulus in the broken bone and possibly also in adjoining long bones. This phenomenon was received with interest by the experimental orthopaedics, and the course of growth after both fractures and other traumata to the extremities has been studied in a large number of investigations from Ollier (1867) up to the present. The hopes of gaining in this way a deepened insight into the nature of skeletal growth and also into the healing of fractures have in some respects been fulfilled, but in others thwarted by inaccurate measuring methods.

The demonstration of this growth acceleration and its mapping by experimental methods has been of considerable practical importance for clinical orthopaedics both at the investigation into the reasons for the frequently occurring difference in bone length and at the treatment of it. The study of retarded growth has, of course, correspondingly given valuable information in the mentioned respects.

A person whose arm lengths differ by a few cm. is often unconscious of it as are those around him. It is natural therefore that arm length differences were earlier rarely mentioned, much less reported and Ehalt (1958) observes *en passant* "Verkürzungen bzw. Verlängerungen an der oberen Extremität sind uninteressant".

Wiberg and Emneus at the Orthopaedic Clinic in Lund started in 1955 systematic investigations of the length conditions in growing humerus after fracture. This bone was chosen for the following reason.

Three distinctly different types of fracture in humerus appear in children: metaphyseal fractures through the surgical neck, metaphyseal fractures through the supracondylar region, the genuine diaphysis fracture (the epicondylar fractures are disregarded here). Comparison between the degrees of growth increase at these three types of fractures could be thought to disclose whether the localization of the fracture in relation to proximal and distal epiphyses has any relation to the extent of the growth stimulus, more briefly, whether the growth increase varies with the level of the fracture.

At the 28th assembly of the Nordisk Ortopedisk Forening held in Helsinki in 1956, where growth problems were among the main themes, Emneus submitted a first preliminary report concerning these investigations. Forty instances of fractured humerus were accounted for, where all three of the above mentioned types of fractures were represented and where the length of humerus was established by roentgenological measurement according to orthodiagraphic method. Only one measurement was made

in each case and this had taken place 18 months to 8 years after the accident. The result of the investigation was briefly that overgrowth of 3 to 20 mm could be demonstrated in 34 cases and that no relation between the degree of dislocation of the fracture and the growth acceleration could be proved. Otherwise the limited material permitted no conclusions about a possible relation between fracture level and growth increase.

At the SICOT congress in Barcelona in 1957 *Emneus* and *Wiberg* presented a more detailed report on the effect of fractures on the growth in humerus. As with the Helsinki report two problems were posed:

1. How often does an increase in growth occur after fracture in growing long bone?
2. Does a possible increment in length vary with the fracture level?

This time an attempt had been made to carry out a more detailed investigation by repeated measurements with regular time intervals. This procedure also meant that the answer to a further question could be sought:

3. When does the growth acceleration begin and when does it end?

The material now consisted of 49 cases and increase in length could be demonstrated in 44 of them. The interval between trauma and measurement varied in this series from 18 months to 9 years.

Question 2 could not be answered definitely. The values of the measurements obtained were not considered to provide positive evidence of any relation between the size of the growth stimulus and the level of the fracture.

To find an answer to question 3 an attempt had been made to carry out humerus measurements at three month intervals during the course of approximately 18 months beginning 2—4 months after the accident. Only 5 patients had made themselves available. Only one of these came to all 6 investigations. The obtained diagrams of the increase in growth were therefore highly approximative. The time when measurable accelerated growth began seemed to be 4, possibly 2 months after the accident. With equally strong reservations for insufficient number of measurements the growth stimulus could be supposed to continue for 2 years after the trauma, naturally providing that the growth plates in humerus still remained open.

Emneus and *Hedstrom* published a supplementary report in 1964. The material had now increased to 70 fractures (44 supracondylar, 11 diaphyseal, 15 through the surgical neck) and overgrowth was measured in 63 cases. Measurement series had to a large extent been attempted at regular intervals and 21 growth diagrams — considerably defective in parts —

could be presented. From these the authors believed they could interpret that growth stimulation (counted from the day of the fracture) went on for 12 months in 6 cases, 18 months in 10, and even longer in 4. As in the two previous investigations, it was not possible with any degree of certainty to determine when the growth stimulus starts, nor did the fracture level show any obvious relation to the size of the increase in growth in this series.

The above-mentioned three sub-reports had thus only roughly answered the posed questions. It was thought reasonable, however, that continued work along the given lines should make possible better statistical evaluation and result in one or more scientifically valid conclusions. This continued and intensified investigation is reported in this paper. The approach to the problems has been amplified somewhat. Solutions of the following questions have been sought:

- 1 Is growth stimulus after fracture in growing humerus a constant phenomenon?
- 2 Does this growth stimulus vary with
 - a) the degree of dislocation?
 - b) the distance of the fracture from the growth regions?
 - c) the age of the individual?
- 3 How soon after fracture can growth stimulus be demonstrated and when does it end?
- 4 Does the thus developed bone length difference show signs of adjustment during the continued course of growth?

The investigation is thus primarily of a clinical character, and this aspect is reported in the following *Part One*.

At a relatively early stage of the investigation it became evident that the clinical material was not sufficient to provide answers to all the problems stated above, esp. question 2 b. Consequently experimental studies were introduced as a complement. This experimental work is reported in *Part Two*.

PART ONE

Growth Stimulation After Humerus Fractures in Children

CHAPTER I

EARLIER STUDIES OF ACCELERATED GROWTH IN HOMO, WITH SPECIAL REFERENCE TO FRACTURE

A Normal phenomena of importance when appraising growth stimulus

1 Physiological anisomelia

A difference in length between two equivalent contralateral long bones or extremities — anisomelia — can, of course be conspicuous as in congenital hypoplasia or aplasia, after early poliomyelitis, &c but mostly the differences found are comparatively small being only a few per cent of the total length of the bone in question. If we wish to determine whether a growth stimulation is the cause of the small recorded difference in length we must know the mutual length proportions of the measurement objects at the time the stimulating factor begins to act. In several clinical and experimental studies of skeletal growth however, it has been presumed that the length of equivalent long bones from the right and the left sides of the body is identical. According to several scientists, this presumption is not justified. On the contrary a physiological anisomelia seems to be possibly just as common as a real isomelia. *Bristow* (1909) at direct measurement of femora in an obduction material found an average difference in length of 3 mm in 68 per cent. *Levander* (1929) established with the aid of rontgenological measurement an average variation in femur of ± 2 mm in 6 out of 20 persons (30 %).

Rush & Steiner (1946) measured rontgenographically 1 000 soldiers chosen at random and demonstrated different leg lengths in 77 per cent with an average deviation of 7 mm. *Hjort Guldhammer* (1963) examined an archaeological skeletal material of femora from 102 persons and tibiae from 78. He recorded for both kinds of long bones an anisomelia in 89 per cent where, however, in approximately 50 per cent the difference in length did not exceed 2 mm.

Similar to other growth studies there has not been any great interest in

the upper extremities in this respect, and no exact values concerning physiological anisomelia in humerus have been found in the literature. None the less it is reasonable to presume a certain normal mutual variation in length of this bone.

Before the study of the growth disturbances in the long bones is subjected to a historical survey it must thus be concluded that full symmetry cannot be depended on between the two sides of the body, as far as the length of the skeletal parts is concerned.

2 Different growth intensity in the proximal and the distal bone ends

At a more close analysis of accelerated growth it is important to take into consideration that the increase in length does not occur at an identical rate from the proximal and the distal growth regions of the long bones. Hales (1731) and Duhamel (1742-1743) who investigated skeletal growth were the first to report this in the literature. It has gradually become the object of more precise determinations. With the aid of various kinds of indicators placed in the diaphysis and by direct or roentgenological measurement the approximate values for the percentage proportion of the growth from each epiphyseal plate have been obtained although the values diverge somewhat in different series (for homo Digby 1916, Bergmann 1928, Gill & Abbot 1942, Hendryson 1945, Green & Anderson 1947, Goff 1960, Anderson, Green & Messner 1963). The values for humerus (total growth) are given by two of those authors.

	Proximal growth plate	Distal growth plate
Digby	80	20
Bergmann	75	25

Digby used *can a nutritia* as indicator. Hendryson found this unreliable. Bergmann on the other hand used metaphyseal condensation lines appearing on the roentgen pictures as foundation for his measurements. On the basis of these investigations the total growth proportion from the proximal end of humerus in homo thus seems to be 3-4 times larger than from the distal.

Here it can be noted that the growth activity from the ends of the long bones does not cease at the same time which as far as humerus is concerned is shown in Fig. 4. Huruphry's observation from 1861 should also be mentioned that the epiphyseal plate with the lower growth potential is the one which becomes obliterated first.

CHAPTER I

EARLIER STUDIES OF ACCELERATED GROWTH IN HOMO, WITH SPECIAL REFERENCE TO FRACTURE

A Normal phenomena of importance when appraising growth stimulus

1 Physiological anisomelia

A difference in length between two equivalent contralateral long bones or extremities — anisomelia — can, of course, be conspicuous as in congenital hypoplasia or aplasia, after early poliomyelitis, &c but mostly the differences found are comparatively small, being only a few per cent of the total length of the bone in question. If we wish to determine whether a growth stimulation is the cause of the small recorded difference in length, we must know the mutual length proportions of the measurement objects at the time the stimulating factor begins to act. In several clinical and experimental studies of skeletal growth however it has been presumed that the length of equivalent long bones from the right and the left sides of the body is identical. According to several scientists this presumption is not justified. On the contrary, a physiological anisomelia seems to be possibly just as common as a real isomelia. *Bristow* (1909) at direct measurement of femora in an obduction material found an average difference in length of 3 mm in 68 per cent. *Levander* (1929) established with the aid of roentgenological measurement an average variation in femur of ± 2 mm in 6 out of 20 persons (30 %).

Rush & Steiner (1946) measured roentgenographically 1 000 soldiers chosen at random and demonstrated different leg lengths in 77 per cent with an average deviation of 7 mm. *Hjort Guldhammer* (1963) examined an archaeological skeletal material of femora from 102 persons and tibiae from 78. He recorded for both kinds of long bones an anisomelia in 89 per cent where however, in approximately 50 per cent the difference in length did not exceed 2 mm.

Similar to other growth studies there has not been any great interest in

et al (1963) Venous stasis produced by vessel ligation or by tourniquet has been tried by *inter al* Borel (1922) Bergmann (1931) Kishikawa (1936) Seruelle (1948), Hutchison & Burdeaux (1954) Hansson (1969 in press)

Concerning inflammatory stimuli the growth stimulating effect of diaphyseal osteomyelitis was observed early probably first by Stanley (1849) later by Paget (1863) Ollier (1867) Bergmann (1931) and Trueta (1953) *M Brattstrom* (1963) established growth increase in femur and to some extent in tibia at juvenile rheumatoid gonarthrititis — An effect probably related in nature was obtained at the many experiments carried out by the implantation of diverse materials foreign to the body juxta epiphysially or intramedullarily (see e.g. Meusenbach 1910 Pitzen 1928 Bohlmann 1929 Kishikawa 1936 Wu & Milner 1937 Chapchal & Zeldenzust 1948 Pease 1952 Nordentoft & Guldhammer 1964) Heating of growth zones according to Ring & Lee (1958) causes no growth reaction whereas Richards & Stofer (1959) found obvious growth increase after electrical heating Barr *et al* (1943) reported no or negative effect from roentgen radiation Growth increase on the basis of neoplastic changes was recorded by Harris (1962) in fibrous dysplasia McCarroll (1950) *inter al* noted several instances of bone hypertrophy in neurofibromatosis (von Recklinghausen's disease)

The effect of fractures on skeletal growth the main theme of the present work is discussed in more detail in Section 2 (p 16) A closely related lesion the one produced when cutting out tibial grafts was shown to cause moderate growth increases in series published by Compere & Adams (1937) and Breine & Johansson (1966)

The experimental reproductions of traumatic stimuli whether artificial fractures drillings periosteal strippings or other are discussed in *Part Two* where the author describes his use of such a method of producing growth increase in long bone in rabbit

Polioomyelitis as a growth stimulating factor is in parentheses in the above table because this disease when paralysis and trophic disturbances have become fully developed regularly results in growth inhibition However a temporary acceleration of the growth is often noted (Ollier 1867 Lerique 1956 Trott *et al* 1958 Ratliff 1959 Ring 1961) in the paralysed extremity during the first year after the onset of the disease The causal connexion is not fully clear here

Many investigators have attempted in experiments to imitate the polioomyelitis lesions by cutting anterior nerve roots or peripheral nerves Conflicting results were obtained concerning growth stimulus Ring (1961) and Swiden (1967) demonstrated increased growth after the two mentioned

B Survey of the literature concerning stimulation of skeletal growth

1 Brief summary of earlier studies of bone growth stimulation in general

The literature on accelerated growth has with time become copious. Extensive reviews have been given by several authors. For comprehensive surveys the reader is referred to *inter al* Goff (1960), Taillard & Morin (1965), Hansson (1967), Sunden (1967).

At a closer examination of the factors that can stimulate bone growth four main types can be distinguished. These are clinically represented, and are thus based on different pathological changes. For study purposes, experimental correspondences to these categories have been developed, i.e. various types of operations, some of which have found clinical application. The following table shows the clinically occurring growth accelerating stimuli and their experimental equivalents. A fifth category — with sometimes stimulating, but more often inhibiting effect — has been added in parentheses.

Clinically occurring stimuli Experimental stimuli

congenital	arteriovenous fistula venous stasis
inflammatory	implantation of foreign material heat roentgen
neoplastic	no correspondence
traumatic	experimental fractures, periosteal stripping trauma to bone marrow
(poliomyelitis)	different examples of lesions of peripheral nerves

Among stimuli of congenital nature occurring clinically can be mentioned Klippel-Trenaunay's (1900) syndrome with cutaneous haemangioma, varicose veins, and local hypertrophy. Haemophilia has been reported to result in increased growth of long bones on both sides of an arthropathic joint, usually the knee joint (*inter al* Taillard & Morscher 1965). With regard to experimental equivalents vascular deformities have been reproduced by many investigators such as Janes & Musgrove (1950), Hiortorn (1957), Doerr & Janes (1959), Kelly, Janes & Peterson (1959), Vanderhoeft, Kelly,

et al (1963) Venous stasis produced by vessel ligation or by tourniquet has been tried by *inter al* Borel (1922) Bergmann (1931) Kishikawa (1936) Seruelle (1948) Hutchison & Burdeaux (1954) Hansson (1969 in press)

B Survey of the literature concerning stimulation of skeletal growth

1 Brief summary of earlier studies of bone growth stimulation in general

The literature on accelerated growth has with time become copious and extensive reviews have been given by several authors. For comprehensive surveys the reader is referred to *inter al* Goff (1960), Taillard & Morscher (1965), Hansson (1967), Sundén (1967).

At a closer examination of the factors that can stimulate bone growth four main types can be distinguished. These are clinically represented and are thus based on different pathological changes. For study purposes, experimental correspondences to these categories have been developed, i.e. various types of operations, some of which have found clinical application. The following table shows the clinically occurring growth accelerating stimuli and their experimental equivalents. A fifth category — with sometimes stimulating, but more often inhibiting, effect — has been added in parentheses.

Clinically occurring stimuli Experimental stimuli

congenital	arteriovenous fistula venous stasis
inflammatory	implantation of foreign material heat, roentgen
neoplastic	no correspondence
traumatic	experimental fractures, periosteal stripping trauma to bone marrow
(poliomyelitis)	different examples of lesions of peripheral nerves

Among stimuli of congenital nature occurring clinically can be mentioned Klippel-Trenaunay's (1900) syndrome with cutaneous haemangioma, varices, and local hypertrophy. Haemophilia has been reported to result in increased growth of long bones on both sides of an arthropathic joint, usually the knee joint (*inter al* Taillard & Morscher 1965). With regard to experimental equivalents, vascular deformities have been reproduced by many investigators such as Janes & Musgrove (1950), Hierton (1957), Doerr & Janes (1959), Kelly, Janes & Peterson (1959), Vanderhoeft, Kelly

of the cases had undergone osteosynthesis with Lane plate which can in itself be thought to stimulate growth

Shortly afterwards *Burdick & Siris* (1923) reported a large material of fractures of the shaft of femur in children. Of these 118 had at discharge from hospital a shortening of the bone of 0.5 to 3 cm (the measuring method is not described). Within 3 years 53 of them had spontaneously attained bone length equality, and 14 others showed obvious reduction in the length difference. The authors make no theoretical deliberations instead they draw the practical conclusion that a slight shortening in fractures of this nature must not necessarily be corrected.

In 1923 *Speed* published an article wherein he mainly discussed overgrowth in relation to osteomyelitis but where in the introduction he mentioned in passing that he had observed about 20 cases of so called compensatory overgrowth which refers precisely to these growth accelerations in fractured (and primarily shortened at healing) femora. In 1924 *David* reported a series of 71 diaphyseal femur fractures where with the aid of repeated roentgenological measurements he could demonstrate that 62 of them completely or partly had been able to correct the reduction in the length of the fractured bone that existed at the end of the fixation treatment.

Cole (1922-1925) presented smaller series also measured roentgenologically and made in the main the same findings as *David* but also noted in 2 cases of fractured femur that not only femur but also tibia on the same side had increased in length. *Connell* (1929) was of the opinion that skeletal overgrowth chiefly occurred before 8 years of age. *Clark* (1926) out of 31 cases of fractured femur could not find any with increase in growth.

An interesting analysis was published in 1929 by *Letander*. In a thesis on the treatment of shaft fractures of the femur a special chapter referred to increased growth in length of the long bones of the lower extremity after fracture. As mentioned earlier (p. 12) *Letander* began his investigation by determining the possible occurrence of physiological difference in length between contralateral equivalent long bones in a normal material to enable him to stand on firmer ground at a following measurement of the fracture cases. The values obtained for physiological anisomelia however were negligible. Determinations of bone length were then carried out by roentgenological measuring technique on 48 femur fracture patients aged from 1 to 16 years of whom 46 showed positive increase in length varying from 4 to 40 mm. No obvious relation between the extent of the added length and the localization, form and treatment of the fracture could be proved nor

forms of motor denervation, whereas Gillespie (1954) Troupp (1961), *inter al*, observed growth inhibition Lumbar sympathectomies have often resulted in insignificant or no overgrowth (Cannon *et al* 1929, Bisgard 1933, Kishikawa 1936, Harris & McDonald 1936 Ring 1961)

This section has thus, in a brief survey, dealt with forms of natural and artificial growth acceleration that are not immediately related to the present author's own investigations

2 Earlier investigations of the growth stimulating effect of fractures

Most investigations published in Anglo Saxon, French German and Scandinavian literature which treat overgrowth after fracture refer to femur, whereas few deal with tibia, radius, and ulna Humerus has not been the object of any special study, except for the earlier mentioned investigations by Emneus (1956) Emneus & Wiberg (1957), and Emneus & Hedström (1964) Brief references are made in passing to humeral overgrowth by Budig (1957), Ratanelli & Prinstl (1958) and Murayama (1963) A larger investigation of more fundamental nature into growth acceleration, in which humerus was also examined was published in 1959 by Calati & Poli and is referred to in more detail on p 21

There is no reason for supposing that essential differences could exist concerning the growth conditions for various kinds of long bones When a survey of the studies in this field — mainly concentrated to femur — is now presented the intention is that facts and hypotheses extracted therefrom should then form a discussion basis for the present author's analysis of the post-traumatic growth stimulus in humerus

Ollier is often described as the discoverer of the growth increase after fracture of growing long bones However the phenomenon has been known earlier it was mentioned by Volkmann (1862) From Ollier's much varied and well documented studies from 1867, we learn that fracture in growing femur or tibia can result in at least 1 cm increase in length v Langenbeck in 1869 observed that increased longitudinal growth can occur after contusion of the diaphysis regions During the next decades, similar individual reports appeared (e.g Carlsson 1918), usually as marginal notes to records of treatment and treatment results in femur fractures

Truesdell (1921) was the first to use the post traumatic increase in growth as a theme for an article Without describing his measuring technique he presented 5 cases of femoral shaft fracture with on average 2.5 cm increase in length The observation does not permit any conclusions especially as 2

of the cases had undergone osteosynthesis with Lane plate which can in itself be thought to stimulate growth

Shortly afterwards *Burdick & Siris* (1923) reported a large material of fractures of the shaft of femur in children. Of these 118 had at discharge from hospital a shortening of the bone of 0.5 to 3 cm (the measuring method is not described). Within 3 years 53 of them had spontaneously attained bone length equality and 14 others showed obvious reduction in the length difference. The authors make no theoretical deliberations; instead they draw the practical conclusion that a slight shortening in fractures of this nature must not necessarily be corrected.

In 1923 *Speed* published an article wherein he mainly discussed overgrowth in relation to osteomyelitis but where in the introduction he mentioned in passing that he had observed about 20 cases of so called compensatory overgrowth which refers precisely to these growth accelerations in fractured (and primarily shortened at healing) femora. In 1924 *David* reported a series of 71 diaphyseal femur fractures where with the aid of repeated roentgenological measurements he could demonstrate that 62 of them completely or partly had been able to correct the reduction in the length of the fractured bone that existed at the end of the fixation treatment.

Cole (1922, 1925) presented smaller series also measured roentgenologically and made in the main the same findings as *David* but also noted in 2 cases of fractured femur that not only femur but also tibia on the same side had increased in length. *Conwell* (1929) was of the opinion that skeletal overgrowth chiefly occurred before 8 years of age. *Clark* (1926) out of 31 cases of fractured femur could not find any with increase in growth.

An interesting analysis was published in 1929 by *Leander*. In a thesis on the treatment of shaft fractures of the femur a special chapter referred to increased growth in length of the long bones of the lower extremity after fracture. As mentioned earlier (p. 12) *Leander* began his investigation by determining the possible occurrence of physiological difference in length between contralateral equivalent long bones in a normal material to enable him to stand on firmer ground at a following measurement of the fracture cases. The values obtained for physiological anisomelia however were negligible. Determinations of bone length were then carried out by roentgenological measuring technique on 48 femur fracture patients aged from 1 to 16 years of whom 46 showed positive increase in length varying from 4 to 40 mm. No obvious relation between the extent of the added length and the localization, form and treatment of the fracture could be proved nor

any relation to the age of the patient. The duration of the growth acceleration was estimated at 2 to 3 years. Of the patients, 8 were also investigated concerning possible increase in length of tibia in the fractured extremity; growth increase of 3 to 7 mm. was established in 5 patients.

Contrary to *Speed*, *Cole*, and others, who regarded increase in growth after fracture as compensatory and possibly conditioned by mechanical causes, *Levander* believed that the increase in growth was triggered off by post-traumatic hyperaemia in and around the fractured bone, and seems to have been the first to propound this theory. It is true that *Lexer* in 1922 was able to demonstrate a marked and long lasting increase in the vascularity around fractures, but he did not associate this with the phenomenon of overgrowth. In the same investigation *Levander* tried to support his hypothesis by the use of experimental studies (these are reported in Part Two). In his summary, *Levander* concluded that growth stimulus after fracture of growing long bone was a constant phenomenon and that its duration was 2—3 years; moreover, fracture of a long bone under certain, unknown conditions could also result in an increase in growth in other long bones in the same extremity.

Ferguson (1933), finding that after tibia osteotomy in children a relative reduction in the fibula of the same side could be noted, realized that this must be due to accelerated growth of the operated tibia and developed on the basis of this observation a theory that the increase in growth must be conditioned by the interrupted blood supply from the medullary vessels to the metaphysis and by redirection resulting from this of blood to the still intact periosteal and epiphyseal vessels. The same line of reasoning could apply to the growth stimulus in diaphyseal fractures. On the basis of this he developed an operation method for producing bone elongation: drilling of the cortex and curettage of the medulla via the drilled hole. Increases of growth of 2—3 mm. could be recorded.

The works of *Ferguson* and *Levander* as well as experimental studies by *Bisgard* (1936), *Kishikawa* (1936), *Wu & Miltner* (1937) and *Compere & Adams* (1937) resulted in the vague theory of compensatory increase in growth being abandoned. Instead the circulation disturbance and the periosteal injury produced by the trauma began to be held mainly responsible for overgrowth after fracture.

Aitken in 1940 published a follow-up investigation of 65 femur fractures in children. Of these 8 had been operated on; all showed marked increase in growth, whereas of the remaining 57 treated conservatively 55 showed added length of varying degree. A fairly detailed article about growth increase was published by *Blomquist & Rudstrom* in 1943. An analysis was

made of 50 cases all femur fractures Regarding age the largest average growth stimulus occurred in the age groups 2—4 years and 6—10 years The increase in length in these ages averaged 12 mm (rontgenological measuring method) Only 7 cases showed no or uncertain overgrowth The growth acceleration which in many instances was demonstrable up to 2 years after the accident, was usually most pronounced during the first year The material included 11 operated patients and those of them who had undergone osteosynthesis showed high values of overgrowth The authors also used these osteosynthesis cases as a control of *Bergmann's* (cf p 13) determination of the different growth proportions from proximal and distal cartilage plates and obtained similar results *Hedberg* (1944) examined a material of 44 femur fractures in children and found growth increase in 38 of them with an average value of 9 mm Increase above the average value was found in the ages 4—8 years

During the past two decades several articles have appeared wherein fundamentally similar results have been published (see for instance *Oeconomos* 1948 *Lorthioir & Soeur* 1948 *Potts & Dunham* 1949 *Schluttemeyer & Flach* 1950 *Odell & Leydig* 1951 *Greville & Iums* 1957 *Neer & Cadman* 1957 *Pease* 1957 *Schenk* 1957 *Ingelrans Lacheretz & Poupard* 1958 *Calati & Poli* 1959 *Netes* 1959 *Krebs & Streicher* 1960 *Singer & Kraft* 1961 *Vontobel Genton & Schmid* 1961 *Flach & Kudlich* 1962 *Henry* 1963 *Weber* 1963 *Miyagi & Murayama* 1964 *Greue & Niemann* 1966 *Flach Geisbe & Fendel* 1967)

A systematic survey of all these articles however would take up too much space apart from adding nothing essentially new to the discussion but for the sake of greater surveyability a summary of the gained results is given at the end of this section None the less there is reason to refer specially to *W. P. Blount's* activity within bone growth research Although this particularly aims at the treatment of bone length difference he has in several articles (1944 1950 1952 1960) and not least in his monography *Fractures in Children* (1954) disseminated knowledge of the increased growth after fractures in growing bone and has suggested how this can be prevented from reaching dimensions disturbing to the static conditions of the individual According to *Blount* open repositions of diaphyseal fractures are practically never indicated they are associated with the risk of especially strong increase in growth Repeated correcting manipulations during the course of healing have the same damaging effect Although *Blount* finds the size of the growth increase difficult to appraise beforehand he recommends that the diaphyseal femur fractures in children be allowed to heal with a reduction of 1—2 cm which will highly probably be

any relation to the age of the patient. The duration of the growth acceleration was estimated at 2 to 3 years. Of the patients 8 were also investigated concerning possible increase in length of tibia in the fractured extremity; growth increase of 3 to 7 mm. was established in 5 patients.

Contrary to *Speed*, *Cole*, and others, who regarded increase in growth after fracture as compensatory and possibly conditioned by mechanical causes, *Levander* believed that the increase in growth was triggered off by post-traumatic hyperaemia in and around the fractured bone, and seems to have been the first to propound this theory. It is true that *Lexer* in 1922 was able to demonstrate a marked and long-lasting increase in the vascularity around fractures, but he did not associate this with the phenomenon of overgrowth. In the same investigation, *Levander* tried to support his hypothesis by the use of experimental studies (these are reported in Part Two). In his summary, *Levander* concluded that growth stimulus after fracture of growing long bone was a constant phenomenon and that its duration was 2—3 years; moreover, fracture of a long bone under certain unknown conditions could also result in an increase in growth in other long bones in the same extremity.

Ferguson (1933), finding that after tibia osteotomy in children a relative reduction in the fibula of the same side could be noted, realized that this must be due to accelerated growth of the operated tibia and developed on the basis of this observation a theory that the increase in growth must be conditioned by the interrupted blood supply from the medullary vessels to the metaphysis and by redirection resulting from this, of blood to the still intact periosteal and epiphyseal vessels. The same line of reasoning could apply to the growth stimulus in diaphyseal fractures. On the basis of this he developed an operation method for producing bone elongation: drilling of the cortex and curettage of the medulla via the drilled hole. Increases of growth of 2—3 mm. could be recorded.

The works of *Ferguson* and *Levander* as well as experimental studies by *Bisgard* (1936), *Kishikawa* (1936), *Wu & Miltner* (1937) and *Comperc & Adams* (1937), resulted in the vague theory of compensatory increase in growth being abandoned. Instead the circulation disturbance and the periosteal injury produced by the trauma began to be held mainly responsible for overgrowth after fracture.

Aitken in 1940 published a follow-up investigation of 65 femur fractures in children. Of these 8 had been operated on; all showed marked increase in growth, whereas of the remaining 57 treated conservatively 55 showed added length of varying degree. A fairly detailed article about growth increase was published by *Blomquist & Rudstrom* in 1943. An analysis was

although such was recorded in 4 out of 53 cases it was judged to have no significance

A very extensive literature treats humerus fractures in children particularly supracondylar fractures but the interest is as a rule directed on therapeutic problems and as already indicated there is usually no information about stimulus of the longitudinal growth of humerus The author could trace only 3 works that discussed this phenomenon

In 1957 *Budig* reported the final results of a great many instances of epiphyseolysis and fracture close to or involving the proximal growth plate of humerus Regarding the former he established as expected a number of growth reductions because of the epiphyseal lesion When *Budig* similarly measured the pure fracture cases which thus showed fracture through the surgical neck he found out of 50 patients 7 with elongation of the humerus amounting to up to 3 cm A number of reduction were also recorded in the same group probably due to the fractures having engaged the growth region without this appearing in the roentgen pictures

In a follow up study of supracondylar humerus fractures from 1958 *Ravanelli & Prinzi* observed an increase in width metaphysially in 46 % of the patients Length measurement however was not made

Calati & Poli in 1959 presented a material of 165 roentgenologically measured diaphysis fractures from femur tibia humerus radius/ulna and clavicle They found different frequencies for growth increase in these bones for femur and tibia 63.6 % and 60 % respectively for humerus 27.7 % and for clavicle zero At the same time they admitted that the percentage can be higher because fractures that heal with considerable shortening can be thought to trigger of an overgrowth although not large enough for the fractured bone to become equally as long as or longer than the bone on the healthy side The absolute size of overgrowth was found to be larger for femur and tibia than for the long bones of the arms The authors considered that elongation resulting from growth stimulus is probably permanent that metaphyseal fractures produce slighter increase in growth than do diaphyseal fractures and that the added length is possibly proportional to the dislocation of the fracture and the extent of periosteal lesion Concerning the genesis of the changed growth rate the authors discuss *Trueta's* theory about the destruction of the nutritional circulation and the increased blood supply to the growth region This theory is set against the hypothesis of *Lacroix* concerning a specific agent that stimulates bone formation osteogenin which could be released in the fracture and which possibly could not only have an effect on the fractured bone but also perhaps exert some remote effect on the skeleton as a whole Some

eliminated during the course of further growth. The same author cannot demonstrate any relation between the distance of the fracture from the growth plates and the size of the overgrowth, he finds no tendency for spontaneous recovery of the difference in length arising from growth stimulus.

Two works of Danish authors are worthy of a more detailed examination. Both are specially devoted to the growth stimulus after fracture. *Barfod & Christensen* in 1958 published a follow-up study of 114 femur fractures, wherein, however, they restricted themselves to the use of a tape measure as measuring method, this obviously limits the value of the investigation. Contrary to most earlier investigators they separated conservatively treated from operatively treated. At a follow-up study, both categories showed overgrowth, although this was considerably more pronounced in the operated cases. The growth stimulus was judged to last for about 2 years. Oblique and comminute fractures were shown to produce more overgrowth than transverse fractures, whereas there was insufficient material to enable them to decide the possible importance of the position of the fracture in relation to the growth regions. No positive sex difference could be demonstrated, whereas concerning the effect of age, it was possible to record that children less than 3 years of age showed slightly weaker increase in growth after trauma than did the age group 3—15 years, where the growth acceleration appeared both more rapid as well as fairly homogeneous. Elongation of the tibia of the same side, in femur diaphysis fracture occurred in 6 out of 93 cases, with values lying between 5 and 10 mm.

In 1963, *Hjort Guldhammer* presented a thesis devoted to growth stimulus after fracture in the lower extremity in children. The investigation was based on orthodiagraphic length determinations, mostly single measurements made at different time intervals after the trauma, but also series of repeated measurements. Compared with investigations referred to earlier much information is obtained concerning the effect of tibia fractures on growth. Fairly regularly *Hjort Guldhammer* found increase in growth in tibia after dislocated transverse or oblique fracture averaging 8 mm. At non-dislocated fracture on the other hand the bone length increases on average 3 mm. The growth acceleration is said to start immediately after the trauma and stops within the course of 18 to 24 months. The average overgrowth for femur is determined at 13 mm for dislocated fractures but at zero for infraction. Children aged 0—4 years have a growth increase averaging 11 mm, children more than 4 years 14 mm. No ipsilateral growth stimulus can be proved in femur at tibia fracture. Conversely, no ipsilateral growth stimulus can be proved in tibia at femur fracture.

although such was recorded in 4 out of 53 cases it was judged to have no significance

A very extensive literature treats humerus fractures in children particularly supracondylar fractures but the interest is as a rule directed on therapeutic problems and as already indicated there is usually no information about stimulus of the longitudinal growth of humerus. The author could trace only 3 works that discussed this phenomenon

In 1957 *Budig* reported the final results of a great many instances of epiphyseolysis and fracture close to or involving the proximal growth plate of humerus. Regarding the former he established as expected, a number of growth reductions because of the epiphyseal lesion. When *Budig* similarly measured the pure fracture cases which thus showed fracture through the surgical neck he found out of 50 patients 7 with elongation of the humerus amounting to up to 3 cm. A number of reduction were also recorded in the same group probably due to the fractures having engaged the growth region without this appearing in the roentgen pictures.

In a follow up study of supracondylar humerus fractures from 1958 *Ratanelli & Primstl* observed an increase in width metaphysially in 46 % of the patients. Length measurement however was not made.

Calati & Poli in 1959 presented a material of 165 roentgenologically measured diaphysis fractures from femur tibia humerus radius/ulna and clavicle. They found different frequencies for growth increase in these bones: for femur and tibia 63.6 % and 60 % respectively for humerus 27.7 % and for clavicle zero. At the same time they admitted that the percentage can be higher because fractures that heal with considerable shortening can be thought to trigger off an overgrowth although not large enough for the fractured bone to become equally as long as or longer than the bone on the healthy side. The absolute size of overgrowth was found to be larger for femur and tibia than for the long bones of the arms. The authors considered that elongation resulting from growth stimulus is probably permanent: that metaphyseal fractures produce slighter increase in growth than do diaphyseal fractures and that the added length is possibly proportional to the dislocation of the fracture and the extent of periosteal lesion. Concerning the genesis of the changed growth rate the authors discuss *Trueta's* theory about the destruction of the nutritional circulation and the increased blood supply to the growth region. This theory is set against the hypothesis of *Lacroix* concerning a specific agent that stimulates bone formation *osteogenin* which could be released in the fracture and which possibly could not only have an effect on the fractured bone but also perhaps exert some remote effect on the skeleton as a whole. Some

support for the existence of such a factor is given by the authors in their observations of so called growth arrest striae (*Harris 1933, Trueta 1953*) not only in the metaphysis of the damaged long bone but also in other long bones in other extremities

Miyagi and Murayama in their study from 1964 have also measured repeatedly about a hundred diaphyseal fractures among them 6 humeri. Overgrowth in this series is common, but not inevitable. It is most pronounced between 3 and 10 years of age, seems to continue for about 3 years and results in permanent elongation. The increase in length in the humerus has in no case exceeded 10 mm.

With the object of getting greater surveyability, it seems desirable here to list present known facts and accepted hypotheses concerning growth stimulus after fracture of growing long bone such as could be derived from monographs and large summary articles by *Goff 1960, Flach & Kudlich 1962, Taillard & Morscher 1965, Flach, Geisbe & Fendel 1967*.

It can be gathered from the literature

that growth stimulus after fracture *does* occur in the long bones of both the lower and the upper extremities

that this growth increase is a frequently occurring possibly regularly appearing phenomenon, provided the fracture is dislocated

that dislocated and/or comminuted fractures are probably accompanied by particularly marked growth stimulus

that children during the first 2—4 years of their life might show comparatively slight growth acceleration

that growth stimulus most often becomes noticeable fairly early in the course of healing probably 2—3 months after the accident

and that it continues as long as reconstruction processes and increased blood circulation occur in the injured bone i.e. *circa* 2 years

that an established length difference is not to any appreciable extent eliminated by some later form of change in growth

However, it is not positively stated in the literature

whether the fracture level in the long bone has any significance for the size of the increase in growth

whether adjoining long bones show to a greater or lesser extent the same increase in growth as the fractured bone

If the problems posed by the present author are set in relation to the investigation results taken from the literature it would seem that the answers to the various questions on p. 10 can in no case be regarded as guaranteed. No correlation between fracture level and growth stimulus has been proved and the relation of the increase in growth to the age of the individual as well as its development in time cannot be considered known with any particular degree of accuracy.

CHAPTER II

MATERIAL

The material consists of humerus fractures. Because certain clinical and anatomical designations or phenomena concerning humerus could call for some comment or definition, it was thought fitting to give a brief introductory description of humerus and of the fracture types discussed in this work. Beside this, it was also judged necessary to define some general concepts about long bones, because the nomenclature varies with different authors. The account is restricted to those phenomena directly related to the objective and the completion of the investigation.

A Some anatomical terms

The terminology used here concerning the main parts of a growing long bone agrees with that used by *Hansson* (1967) in his thesis on longitudinal bone growth in rabbits. Thus according to Fig. 1 there is a distinction between a diaphysis and the two end regions. Reckoned from the middle the diaphysis is composed of the shaft proper and the metaphyses which border on the end regions. In central direction the metaphysis extends as far as the bone substance is spongy in texture. The epiphysis contains a central bone nucleus (in places several) the bony epiphysis surrounded by a cartilaginous shell the growth cartilage of the epiphysis. Between the diaphysis and the bony epiphysis there is a cartilaginous zone from now on called the growth plate which from a physiological standpoint can be considered as consisting of two layers: one terminal belonging to the epiphysis — the growth cartilage of epiphysis — and one central bordering on the diaphysis — the growth cartilage of diaphysis. In the former the

growth occurs distally reckoned from the middle of the bone in the latter centrally. The firstmentioned centrifugal growth is on a small scale and probably ceases altogether early in the life of the individual.

B Some anatomical observations concerning humerus

The almost hemispherical, cartilage covered *caput humeri* is distally delimited by a narrow ring-formed groove, *collum anatomicum*. The cranial part of this groove forms the border between the humeral head and the two

Fig 2 Front of right humerus

- 1 collum anatomicum
- 2 tuberculum majus
- 3 tuberculum minus
- 4 the bicipital groove
- 5 nutrient foramen of the diaphysis
- 6 coronoid fossa
- 7 medial epicondyle
- 8 lateral epicondyle
- 9 trochlea
- 10 capitulum humeri

tuberosities. The greater tuberosity is the large prominence at the upper end of the lateral surface of the humerus. There is no clear distal border to this tuberosity. It slopes in a slight arc down towards the diaphysis.

The minor tuberosity which is separated from the other by the bicipital groove faces directly forwards and its distal border is somewhat more distinct than in the case of the greater tuberosity

Immediately distal to these two tuberosities lies the surgical neck. This section is often not clearly defined concerning its distal delimitation. However the author chooses to define the extent of the surgical neck in accordance with *Anson & Maddock (1933)* from the lower limit of the tuberosities to the insertion of the axillary muscles into the intertubercular sulcus. Unfortunately this limit cannot be distinguished on rontgen pictures of humerus the rontgenological indication of the surgical neck is therefore somewhat optional but no better demarcation line can be proposed

Regarding the proximally cylindrical distally three sided prismatic diaphysis only the position of the nutrient foramen will be dealt with here. *Carroll (1963)* has made a study of the position of this orifice in homo and found that in most instances it is situated within a small area on the medial aspect of the distal half of the middle third of the shaft. Other diaphyseal nutrient foramina macroscopically visible were rare in *Carroll's* material he therefore concludes that the predominant part of the blood supply of the diaphysis and the medulla occurs via the first mentioned, usually medially situated orifice

The border between the diaphysis and the distal metaphysis (the supracondylar zone) in humerus is difficult to establish at external inspection. To count with finger breadths from the joint surface as suggested in some anatomical textbooks is not suitable when referring to a material of growing individuals with big variations in the length of humerus. To indicate the uppermost attachment point for the forearm musculature as upper limit (i.e. the insertion for m. brachioradialis) would mean that a considerable part of what from a clinical standpoint is regarded as diaphysis would be included in the supracondylar region. Instead the author chooses as limit a plane lying at right angles to the longitudinal axis of humerus and passing through the most cranial point of fossa olecrani. This plane can without difficulty be established on the rontgen picture. Regarding the region of the supracondylar humerus fractures however see p 31

The shape of the distal end of the humerus is characterized by the divergence between the radial and ulnar margins already begun in the diaphysis. These margins furthest distally form the lateral and the medial epicondyle between which the deep olecranon fossa lies on the dorsal side and the coronoid fossa on the volar side. In the distal joint surface of humerus there is a radial protrusion with a spherical contour when viewed

Fig 3 The main sources of the arterial supply of the humerus

- 1 main nutrient artery of the diaphysis*
- 2 anterolateral branch of the anterior humeral circumflex artery*
- 3 smaller nutrient arteries of the epicondyles*

from the volar side *capitulum humeri*. In an ulnar direction from this and separated from it by a groove lies the hour-glass shaped *trochlea humeri*.

Laing (1956) has studied the distribution of the arterial vessels in adult humerus. According to him the proximal end of the humerus is richly supplied by branches from a nutrient artery which in its turn issues from the anterior humeral circumflex artery. The nutrient artery which penetrates into the diaphysis via the nutrient foramen could be shown to have

*Fig. 4 Epiphyseal centers of the humerus at an approx age of 13 years

two branches, one larger, ascending towards caput humeri, and one smaller descending with numerous ramifications towards the epicondyles. These in turn receive arteries from outside, which are especially ramified in trochlea and capitulum. The blood supply appears plentiful also in the distal end of the humerus.

Quite strongly varied information concerning times for the appearance and development of ossification centres in the humerus epiphyses is given by different authors (*Paterson 1929, Francis & Werle 1939, Flecker 1943, Elgenmark 1946, Caffey 1956, Haraldsson 1957, &c*), which probably reflects to some extent the considerable individual differences that exist concerning skeletal development. In the present work, only cases with distinct, well developed bone nuclei were meant to be used; thus ossification data in Fig. 4 have been exceeded by a broad margin. Because the bone nucleus in *capitulum humeri* was judged to be insufficiently developed for measuring purposes in individuals aged less than 18 months they have not been included in the material.

C Types of fractures and degrees of dislocation

As pointed out in the introduction this work deals with the growth stimulus in three different types of fractures

- 1 Fractures through the supracondylar zone
- 2 Fractures through the humerus diaphysis
- 3 Fractures through the surgical neck

The region of each of the categories is given schematically in Fig 5 Regarding the supracondylar fractures it was felt justified to abandon to some extent the upper limit of the supracondylar zone — given on p 27 — because it would otherwise have been necessary to regard as diaphyseal several V shaped fractures which have always been clinically interpreted as supracondylar Here every fracture that completely or partly occurs distally of the plane visualized through the uppermost point of *fossa olecrani* is regarded as a supracondylar fracture

Even more important in this context however is the terminal delimitation of the two fracture zones in the ends of humerus It is well known that fractures that engage a cartilage plate result for the most part in slowing or stopping the growth from this region Such a phenomenon is likely to render the judgement of possible growth acceleration more difficult consequently all such case have been eliminated from the material where on roentgen pictures fractures reach or cross over the cartilage plate or where some degree of epiphysiolysis exists

Bearing in mind how relatively close to the growth plate several fractures included here run their course it must be admitted that some slight degree of engagement of the plate itself cannot in some individual instances be altogether excluded Whether a trauma sufficiently strong to result in metaphyseal fracture is also able to cause a slight perhaps microscopic lysis of the adjacent growth plate is not known although clinical experience gives no cause for such a supposition It is most likely the forces that act in the longitudinal direction of the bone that can have a deleterious effect on the growth cartilage (Hueter Volkmann's law cf also Blount 1954 Goff 1960 Arkin & Katz 1965) whereas here we have mainly to deal with forces that diverge from the longitudinal axis of the humerus

Fractures are often classified with reference to the degree of dislocation or angle position to their genesis mechanism &c After attempts at distribu

two branches, one larger, ascending towards *caput humeri*, and one smaller descending with numerous ramifications towards the epicondyles. These in turn receive arteries from outside, which are especially ramified in trochlea and capitulum. The blood supply appears plentiful also in the distal end of the humerus.

Quite strongly varied information concerning times for the appearance and development of ossification centres in the humerus epiphyses is given by different authors (*Paterson 1929, Francis & Werle 1939, Flecker 1942, Elgenmark 1946, Caffey 1956, Haraldsson 1957, &c*), which probably reflects to some extent the considerable individual differences that exist concerning skeletal development. In the present work, only cases with distinct, well-developed bone nuclei were meant to be used; thus ossification data in Fig. 4 have been exceeded by a broad margin. Because the bone nucleus in *capitulum humeri* was judged to be insufficiently developed for measuring purposes in individuals aged less than 18 months, they have not been included in the material.

This division according to dislocation has been carried out in all three investigated types of fractures. It is coarse and schematic. Thus the rotation factor could not be included in the calculation; this is explained by the primary pictures taken of a humerus fracture not usually allowing more than an approximate estimate of rotatory faulty position. Supracondylar fractures and *collum chirurgicum* fractures of the category + however show no signs of appreciable rotation, and concerning the diaphysary fractures in the author's material the only instance of dislocation grade + was rather a fissure without rotatory element.

In the present relatively limited material a division into more than two subgroups would invalidate the statistical analysis which is why an originally planned distribution into three dislocation grades was abandoned.

tion into three different grades according to dislocation, the author, for this investigation, has chosen to distinguish only two categories + and ++

Dislocation grade + means no or insignificant faulty position, with a *dislocation ad latus* less than $1/4$ bone width, *ad axin* less than 15°

Dislocation grade ++ means that any faulty position, in one plane or more is greater than in grade + Here, is thus also included over-riding position, comminuted fractures, &c

Fig 5 Extra epiphyseal fracture zones in humerus (dorsal aspect,
1 the surgical neck
2 diaphysis
3 the supracondylar region

This division according to dislocation has been carried out in all three investigated types of fractures. It is coarse and schematic. Thus the rotation factor could not be included in the calculation; this is explained by the primary pictures taken of a humerus fracture not usually allowing more than an approximate estimate of rotatory faulty position. Supracondylar fractures and *collum chirurgicum* fractures of the category + however show no signs of appreciable rotation and concerning the diaphysary fractures in the author's material the only instance of dislocation grade + was rather a fissure without rotatory element.

In the present relatively limited material a division into more than two subgroups would invalidate the statistical analysis which is why an originally planned distribution into three dislocation grades was abandoned.

D Report of the fracture cases

The patient material used in the present investigation consists of 86 cases. This figure has been reached as follows:

During the period 1955—1966, a total of 305 cases of extra epiphyseal humerus fractures in children was registered at the Orthopaedic Clinic in Lund for follow-up measurement investigation. At this primary selection all instances of multiple fractures, abdominal injuries, complicating diseases, &c. were eliminated. In the main only such cases were included in the present investigation where humerus fracture was the only diagnosis. However, some cases with simultaneous, slight *commotio cerebri* were also included.

Of the above mentioned 305 patients, 204 were roentgenologically measured on one or more occasions. The first measurement was often taken in connexion with the termination of the fracture treatment and did not meet with any particular opposition from the parents. It was most probably interpreted as a stage in normal follow-up of the case in question. However, when systematic repeated roentgen measurements (for further details, see Chapter III) were requested, the co-operation of patients and relatives was considerably more difficult to obtain. This is probably a common experience (cf. *Oeconomus* 1948, *Chigot* 1958) concerning follow-up examinations of fractures in children. The reason is, of course, mainly that these accident cases are so often restored to full function and that follow-up examination is therefore thought by the parents to be unnecessary.

From this, it might be concluded that the patients who, despite the inconveniences, appear for repeated follow-up examinations also represent the most serious injuries and the most pronounced subsequent disorders. However, from the following report it can be seen that the number of fractures of the lower dislocation grade is about equal to the number of more serious dislocated fractures which ought to permit an adequate comprehensive appraisal without appreciable error. It must be mentioned that excessive *sequelae* on the whole do not occur in this material. Operated cases were not included.

As stated, 204 patients underwent roentgenological measurement. Of these, however, no fewer than 101 failed to appear for the second measurement, thus they were excluded from this investigation. Of the remaining 103, 17 took part in only two measurements; this cannot be considered

Age	Supracondylar		Diaphyseal		Coll. ch.		Total	
	♂	♀	♂	♀	♂	♀	♂	♀

Table 1 Distribution of the clinical material according to age, sex and type of fracture

acceptable either. However 6 of the 17 were included. These had the second measurement several years later when the growth stimulus had probably ceased (i.e. after the onset of puberty). Although the course of growth in these patients cannot be followed in detail there are none the less initial and end values for the humerus lengths.

There remains 92 patients 6 of whom were measured twice and the other 86 several times. From these 86 6 were excluded (1 fracture through the growth plate 1 fracture through bone cyst and 4 technically faulty roentgen pictures). Thus 86 humerus fractures are left for the continued discussion. Table 1 shows the distribution of the material on age, sex and fracture. As completion it can be mentioned that the youngest patient was 20 months at the time of accident the oldest was 13 years 10 months.

Although epidemiological analysis of the fracture material does not come within the scope of this work some comments of this nature can be made. Table 1 gives the impression that supracondylar fractures on the average more often affect younger children than fractures through diaphysis and surgical neck. If the mean age is calculated for on one hand instances of supracondylar fracture and on the other the two other categories combined 6.6 years and 9.8 years respectively are obtained a difference with high significance (observed value of statistic $u=5.43^{***}$). No obvious sex differences appear. A first impression from the table that girls are affected by fracture at a later age than boys does not prove valid at statistical

D Report of the fracture cases

The patient material used in the present investigation consists of 86 cases. This figure has been reached as follows:

During the period 1955—1966, a total of 305 cases of extra-epiphyseal humerus fractures in children was registered at the Orthopaedic Clinic in Lund for follow-up measurement investigation. At this primary selection all instances of multiple fractures, abdominal injuries, complicating diseases, &c. were eliminated. In the main, only such cases were included in the present investigation where humerus fracture was the only diagnosis. However, some cases with simultaneous *slight commotio cerebri* were also included.

Of the above-mentioned 305 patients, 204 were roentgenologically measured on one or more occasions. The first measurement was often taken in connexion with the termination of the fracture treatment and did not meet with any particular opposition from the parents; it was most probably interpreted as a stage in normal follow-up of the case in question. However, when systematic, repeated roentgen measurements (for further details see Chapter III) were requested, the co-operation of patients and relatives was considerably more difficult to obtain. This is probably a common experience (cf. Oeconomos 1948, Chigot 1958) concerning follow-up examinations of fractures in children. The reason is, of course, mainly that these accident cases are so often restored to full function and that follow-up examination is therefore thought by the parents to be unnecessary.

From this, it might be concluded that the patients who, despite the inconveniences, appear for repeated follow-up examinations also represent the most serious injuries and the most pronounced subsequent disorders. However, from the following report it can be seen that the number of fractures of the lower dislocation grade is about equal to the number of more serious dislocated fractures, which ought to permit an adequate comprehensive appraisal without appreciable error. It must be mentioned that excessive *sequelae* on the whole do not occur in this material. Operated cases were not included.

As stated, 204 patients underwent roentgenological measurement. Of these, however, no fewer than 101 failed to appear for the second measurement, thus they were excluded from this investigation. Of the remaining 103, 17 took part in only two measurements; this cannot be considered

CHAPTER III

METHODS

A Recording of bone length and longitudinal growth

The earliest growth determinations were made with tape measure and measuring rod which are still largely in use clinically where no higher demands of exactness than ± 5 mm are to be met. But when growth studies and treatment of bone length differences advanced a need for more accurate measuring methods arose. It was then natural to try to devise a radiological technique for exact reproduction in natural size of the skeletal parts of the extremities.

The earliest developed method — telorontgenography, according to Hickey (1923) — attempted to minimize the deformation of the ends of the bone conditioned by oblique rays by maintaining the distance between rontgen tube and film as large as 7 feet or more. However this proved to be impracticable and also not sufficiently exact. Bertrand & Trillat (1948) thus reckoned with an error of 7—8 mm at such femur measuring and this despite a tube distance of 5 metres.

In 1937 Millner described a technique called slit scanography which employed parallel rontgen rays perpendicular to patient and film and produced with the aid of a lead filter furnished with a transverse slit. A curtain of rays falling at right angles to the film was then obtained. This curtain was operated by a motor alongside the object during the exposure. By this procedure terminal magnification and deformation was excluded but at the cost of a fairly complicated apparatus.

The orthodiagraphic method for skeletal measurements developed and modified in various ways by Green, Wyatt & Anderson (1946), Goldstein & Dreisinger (1950), Bell & Thompson (1950), Farril (1953), Taillard (1956), Goff (1960) and others has resulted in simplification of the procedure so that special apparatus is no longer required and the reproduction does not suffer any angle magnification any more than it does at scanography.

examination A distribution of the fracture material according to dislocation grade (Table 2) might be less interesting from a clinical standpoint, but is given because it is an important part of the later discussion (Chapter IV) and then a reference table should prove valuable

	Supracondylar				Diaphyseal				Collum chir

Table II Distribution of the clinical material according to degree of fracture displacement

The treatment of the fractures will not be analysed in detail. However, an examination of category dislocation + all fracture types shows that all these patients were treated solely by fixation (plaster of paris hanging cast abduction splint) without any reposition or traction whatever. Contrary to this all supracondylar fractures of grade ++ have undergone reposition, in 4 patients repeatedly. The fractures through diaphysis and collum chirurgicum of grade ++ are indicated as manually reset in 4 instances, whereas others were successively corrected during treatment with hanging cast abduction splint or wire traction. With some simplification it can thus be said that the fractures of dislocation grade + were all left *in situ*, whereas the fractures of grade ++ were all subjected to reposition in some form.

If the error is small the measuring value can be corrected and then the calculation is based on the deviation of the central beam from the proper measuring point and the distance focus/film and object/film

The distance focus/film was 100 cm during the present investigation. If the distance object/film is estimated at for instance 5 cm, the degree of magnification is approximately 1.20 (cf Fig 7). If the measuring point lies 2 cm from the central beam the error is thus 1 mm for which correction is required.

Fig 7 Measurement error at orthodisgraphy
According to the principle for equiangular triangles
 $e/S = 10/100 \quad e = 0.5$

F = focus in correct position
 F_1 = focus inadvertently moved 5 cm
 e = measuring error

The largest error factor is probably the conscious or unconscious movements that the patient makes during the course of photographing. An insignificant movement of the shoulder easily escapes the notice of the investigator at the moment of exposure but gives considerable misrepresentation on the film. Possibly a variation in breathing phase can also result in some mm displacement of humerus particularly in children with scant development of the diaphragmatic breathing. To reduce the risk of these sources of errors shoulder and wrist were steadied with sandbags but smaller position adjustments can sometimes have occurred without having

Fig 6 Diagrammatic sketch for orthodiagraphical measurement (according to Buchner Radiometrie)

Strongly collimated perpendicular beams are used. As at all geometrical rontgen measurements, accurate adjustment of the patient is essential. The investigated body part must be parallel with the film, which in the case of the humerus means that the distal end must be raised. An estimate of the object/film distance must be made in each individual instance. On one and the same film, separate exposures are made, at humerus investigations two at measurement of leg length three (cf Fig 6). First the tube is centred on one end of the long bone in question, thereafter it is moved to the other end of the bone for a new exposure.

If the central beam goes through the measuring point, the error of method can be estimated at 1 mm. It is thus necessary to know the position of this vertical central beam. At correctly adjusted rontgen tube the beam passes the film at a point in the centre between the reproduced collimator edges. Very often an edge falls outside the film. If this is judged to occur, an extra exposure with very narrow clearance is made with the tube in the same position as mentioned above (Norman 1955).

If the central beam is aimed incorrectly, i.e. away from the vertex of the joint surface of the bone to be measured, the investigation must be redone.

If the error is small, the measuring value can be corrected and then the calculation is based on the deviation of the central beam from the proper measuring point and the distance focus/film and object/film

The distance focus/film was 100 cm during the present investigation. If the distance object/film is estimated at for instance 5 cm the degree of magnification is approximately 1.20 (cf Fig 7). If the measuring point lies 2 cm from the central beam the error is thus 1 mm for which correction is required

Fig 7 Measurement error at orthodiagraphy
According to the principle for equiangular triangles
 $e/5 = 10/100 \quad e = 0.3$

F } focus in correct position
F₁ } focus inadvertently moved 5 cm
e } measuring error

The largest error factor is probably the conscious or unconscious movements that the patient makes during the course of photographing. An insignificant movement of the shoulder easily escapes the notice of the investigator at the moment of exposure but gives considerable misrepresentation on the film. Possibly a variation in breathing phase can also result in some mm displacement of humerus particularly in children with scant development of the diaphragmatic breathing. To reduce the risk of these sources of errors shoulder and wrist were steadied with sandbags but smaller position adjustments can sometimes have occurred without having

Fig 8 Determination of humeral length — distance measured

been noticed which could in turn explain isolated and obviously faulty measuring values where a humerus suddenly shows a reduction in length compared with previous investigation. A change in rotation position of the upper arm results in a varied projection of *capitulum humeri* whose height can accordingly appear somewhat different. This factor was taken into consideration at the investigation and the patients were instructed to rest the backs of their hands on the table.

With the described technique the object is reproduced in natural size and

the sought humerus length can consequently be obtained by measuring directly on the film. A more detailed description of this measuring procedure is necessary (see Fig. 8).

The most distal point in the bone nucleus in *capitulum humeri* (or where ossification has ended) the corresponding point on the articular surface of *capitulum*) is selected as basis. From there the longest rectilinear distance is determined in humerus where the proximal end point is found to be situated on the cranial surface of the bone nucleus in *caput humeri*. The distance thus measured on the roentgen picture represents the maximum length of humerus reduced by the height of the articular cartilages at the ends of the bone. In case the bone nuclei needed for measuring should in some instances be different in size from their contralateral equivalents (in resemblance to the condition at congenital hip joint luxation) this could result in a certain slight roentgenological anisomelia. A possible such phenomenon is not recorded however and if it exists it is eliminated by the repetition of the measurements (cf. p. 42) and by the primary value of the first measurement being used as basis for bone length difference and the following variations then being compared.

The growth measured by this method is the total of metaphyseal and epiphyseal growth in both growth plates of humerus. The epiphyseal growth however is exceedingly small compared with the metaphyseal (Hansson 1967). This remark is motivated by the measuring method used in the experimental part of the work where exclusively metaphyseal growth is recorded (Chapter VIII).

Fig 8 Determination of humeral length — distance measured

been noticed which could in turn explain isolated and obviously faulty measuring values where a humerus suddenly shows a reduction in length compared with previous investigation. A change in rotation position of the upper arm results in a varied projection of *capitulum humeri* whose height can accordingly appear somewhat different. This factor was taken into consideration at the investigation and the patients were instructed to rest the backs of their hands on the table.

With the described technique the object is reproduced in natural size and

All patients were investigated with the same method. The orthodiagraphic pictures were taken by roentgen technicians supervised by the physician responsible for the investigation who ensured that the roentgen tube was correctly adjusted and who examined the pictures obtained. In conjunction with this a clinical examination was made of each proband to check the range of movement in the shoulder joint and the elbow as well as possible faulty positions. On one occasion a moderate *cubitus varus* was observed which aroused suspicion of lesion of the growth plate. Close examination of the primary roentgen pictures of the patient confirmed this supposition; he was therefore excluded from the material. Otherwise 9 cases of slight extension and flexion defects were noted; however in no case of more than 15°. One proband with slight Volkmann's contracture had been included in the primary material but was omitted after the first measurement. 78 probands had completely normal function in the injured arm; no deformity — naturally apart from length discrepancies of varying degree — and no subjective complaints.

Because it could be of importance to find out whether the normally different growth rate from proximal and distal growth plate showed the same or changed proportions after fracture the insertion of a metal indicator in the humerus diaphysis was contemplated. With the aid of this it might be possible to measure the added growth from both directions directly on the roentgen picture. *Blount & Arlitter* in 1959 had constructed an

B Details of the investigation

According to the original plan made in 1956 for these growth studies (see *Emnéus 1956, Emnéus & Wiberg 1957*) the object was to make roentgenological measurements with the time schedule 3—6—9—12—15—18—21—24—30—36 months counted from the time of accident. Thus 10 measurements should be made in each patient, and deviations from the schedule of more than ± 1 week should be avoided. In principle this pattern was maintained during the investigation, although it became evident from the beginning that for several trivial reasons, already mentioned, both large deviations and mainly important restrictions in the measurement programme had to be accepted (see p. 43).

It was also found desirable to make the first measurement considerably earlier than 3 months after the accident if possible as early as one month after the fracture fixation had been removed and the patient had regained enough mobility in his elbow to make roentgenological determination of length possible (i.e. an extension defect of at most 30°). With such an early examination it was hoped that it would be possible to record the humerus length before the growth stimulus had had time to give measurable effect.

To gain information about the final length relations between fractured and uninjured upper arm about 30 patients whose humerus fractures had occurred 6—7 years before and had now finished growing were recalled at the end-phase of the investigation and measured in the same way.

With these additions the ideal measuring schedule appeared as follows 1 (2)—3—6—9—12—15—18—21—24—30—36—72 (84). None of the patients fulfilled completely these demands and only few even approached it (because of reasons mentioned earlier). A table of the distribution of the probands on different numbers of measuring occasions shows that essentially lower investigation frequency than planned had to be accepted.

All patients were investigated with the same method. The orthodiagraphic pictures were taken by roentgen technicians supervised by the physician responsible for the investigation who ensured that the roentgen tube was correctly adjusted and who examined the pictures obtained. In conjunction with this a clinical examination was made of each proband to check the range of movement in the shoulder joint and the elbow as well as possible faulty positions. On one occasion a moderate *cubitus varus* was observed which aroused suspicion of lesion of the growth plate. Close examination of the primary roentgen pictures of the patient confirmed this supposition. He was therefore excluded from the material. Otherwise 9 cases of slight extension and flexion defects were noted however in no case of more than 15°. One proband with slight Volkmann's contracture had been included in the primary material but was omitted after the first measurement. 78 probands had completely normal function in the injured arm, no deformity — naturally apart from length discrepancies of varying degree — and no subjective complaints.

Because it could be of importance to find out whether the normally different growth rate from proximal and distal growth plate showed the same or changed proportions after fracture the insertion of a metal end cap in the humerus diaphysis was contemplated. In the light of this it might be possible to measure the added growth from both distally and directly on the roentgen picture. Brown & Arlitt in 1959 had constructed an

instrument for percutaneous insertion of small stainless steel markers and by courtesy of *Blount* it was possible to test a modification of this. It took the form of an 8 cm long steel pin of 1 mm calibre with a sharp point at one end and a slight indentation encircling it 5 mm above the point. Under the narcosis used for resetting the humerus fracture in question the point should be driven in percutaneously in the middle of the diaphysis whereafter a slight bend would break the pin at the indentation. The point would then remain steady in the diaphysis as a permanent indicator and there would probably be no need to remove it. Several tests were made with this instrument but it was found that the point usually became bent and broke off before becoming sufficiently embedded in the cortex of the bone. It therefore became fastened in the periosteum where it was not a safe fixed point for measuring purposes (cf *Lacroix 1950*). To insert the indicator reliably in the humerus diaphysis a small operative exposure of the bone surface seemed necessary. This however could be sufficient trauma to cause growth disturbance and furthermore could hardly be thought defensible on ethical grounds. There was always the possibility that the presence of a steel pin in the middle of the diaphysis could have some slight effect on the growth (*Tapp 1966* *Hansson 1967*). The experiments were therefore abandoned.

Fig 9 Orthodiagnostic x ray picture for measurement of humerus

The humerus measurements were made with a ruler on the roentgen pictures (Fig 9) against the light. They were made twice and sometimes three times at first by an assistant and then by the author. The measuring values were usually identical or could show a difference of at most 1 mm.

This agrees quite well with earlier indication of the measurement error of 1 mm. At correctly performed roentgen examination this error is entirely conditioned by the impracticability of measuring more accurately than 1 mm even on a roentgen picture of good quality.

Correction motivated by faulty adjustment of the central beam was made in conjunction with the author's measurement but was necessary in rather a few cases because an error of this nature is normally observed at the roentgen examination and would result in a new and more accurate picture being taken.

Occasional absurd measurement values such as length reductions occurred and were attributed to movements made by the patient between the exposures. Such values were excluded at the statistical treatment.

C Statistical methods

The character of the clinical material caused the statistical working model to be of the same type as that used at the appraisal of the experimental material in *Part Two*. Thus a comparison between fractured bone and control bone was made for each patient. However, because the measurements were made at irregular time intervals, difficulties arose at the formulation of universal working models in mathematical symbols. In principle however, the difference

$$d_{ij} = (X_{Fi(j+1)} - X_{Ci(j+1)}) - (X_{Fi} - X_{Ci}) \quad \text{where} \quad \begin{array}{ll} i = 1, 2, 3 & n \text{ (patients)} \\ j = 1, 2, 3 & n \text{ (measuring time)} \end{array}$$

is valid

X_{Fi} is the measuring value for the fractured bone in the i^{th} patient after the j^{th} measuring occasion. X_{Ci} is the measuring value for the control bone in the i^{th} patient after the j^{th} measuring

The analysis was rendered difficult by the variable of the bone length before fracture being completely unknown. In agreement with the planning of the clinical investigation the statistical analysis was thus limited to measurements after the fracture, where the first measurement in most cases took place three months after the trauma.

The purpose of the analysis was an estimate of the size of the added growth on the fractured side and an estimate of the time for maximum overgrowth. Successive differences were established here between consecutive measuring occasions. The method was constructed so that an answer could be expected to the question of when a possible overgrowth is recordable in time and in such a way that it was possible to estimate the total average increase in growth either for the fractured side or for the control side.

Statistical formulae and symbols

The statistical analysis was made by conventional methods whereby the following formulae were preferably used

$$s = \sqrt{\frac{\sum(x - m_x)^2}{n-1}} \qquad t(n-1) = \frac{m - \mu}{s/\sqrt{n}}$$

$$m_d - t_p \cdot (n-1) \frac{s_1}{\sqrt{n}} < \mu < m_d + t_p \cdot (n-1) \frac{s_1}{\sqrt{n}}$$

$$t(n_1 + n_2 - 2) = \frac{(m_1 - m_2) - (\mu_1 - \mu_2)}{s \sqrt{\frac{1}{n_1} + \frac{1}{n}}}$$

$$\text{where } s = \sqrt{\frac{(n_1 - 1) s_1^2 + (n_2 - 1) s_2^2}{n_1 + n_2 - 2}}$$

2 Fract coll chr humeri

This includes 18 cases 7 dislocation grade +, 11 grade ++ Of the patients 15 (83.3%) show an obvious added growth (more than 2 mm) on the fracture side The average final growth increase in category ++ is 9.0 mm (maximum value 21 mm) and for category + 6.8 mm (maximum value 13 mm)

Fig 10 Average overgrowth in mm during consecutive time intervals in humerus after fracture of the surgical neck Dislocation + and ++

At a study of the development of growth increase in relation to time (fig 10) almost significant overgrowth is found approximately 4 months after the occurrence of the fracture and a possible maximum around 12 to 16 months In the continued progress the curve lies above the x axis continuously until about 40 months have elapsed but statistical significance no longer exists then therefore nothing definitely can be said about the time point for the cessation of growth stimulus

Fig 11 Accumulated overgrowth in mm in humerus after fracture of the surgical neck Dislocation + and ++

At calculation of the average accumulated growth increase (fig 11) a final value of 8.3 mm is found after 40 months There is no tendency to regress but this cannot be considered altogether excluded on statistical grounds

CHAPTER IV

RESULTS

A Analysis of the growth reaction on fracture

In the following account, the fractures are distributed on four different categories

- 1 Fract diaphys humeri, dislocation grade + and ++
- 2 Fract coll chir humeri dislocation grade + and ++
- 3 Fract supracond humeri, dislocation grade +
- 4 Fract supracond humeri, dislocation grade ++

The classification according to dislocation, as given in Table 2, is thus partly relinquished. It is obvious that a considerably larger number of cases would have made it possible to retain this original classification for all fracture types. With the present material, however, no meaningful statistical analysis would be possible if categories 1 and 2 above with 18 and 8 representatives respectively were further divided.

1 Fract diaphys humeri

The material on this fracture level includes only 8 patients: 7 with dislocation grade ++ and 1 with grade +. No possibilities for statistical analysis exist here, and graphic representation has not been judged practical either. It can merely be established that all the patients show obvious overgrowth (more than 2 mm) which in 3 cases 21 to 26 months after the fracture reveals a limited tendency to reduce. Average final overgrowth for the 7 cases of dislocation grade ++ is 7.4 mm (the highest value 12 mm) whereas the patient with dislocation grade + has an overgrowth of 5 mm. This difference hardly allows any conclusions concerning the influence of the dislocation on the growth increase.

Fig 14 Average overgrowth in mm during consecutive time intervals in humerus after supracondylar fracture Dislocation ++

in some of the growth curves in *Part Two* (cf p 00) Thus it cannot be excluded that this tendency to a second growth spurt unconvincing as yet does represent a reality where the physiological substratum is unknown

The existence of a tendency to growth retardation contributes to the value of accumulated average growth increase (Fig 13) being small 1.1 mm at the end of the 38th month Corresponding value after 18 months on the other hand is 3.3 mm (individual maximum value 7 mm) For more exact comparison with other fracture categories it would of course have been desirable to adjust the measuring values to the 40th month here too but the composition of the material did not allow this

4 Fract supracond humeri dislocation grade ++

The material consists of 33 cases of which 30 (90.9 %) show obvious growth acceleration Significant growth increase (Fig 14) can be established

Fig 15 Accumulated overgrowth in mm in humerus after supracondylar fracture Dislocation ++

3 *Fract supracond humeri dislocation grade +*

Out of 27 patients, 17 (63 0 %) show obvious added growth in the fractured bone from 9 to 18 months after the injury. The growth in relation to time (Fig 12), is almost significantly increased in the time interval 9—14

Fig 12 *Average overgrowth in mm during consecutive time intervals in humerus after supracondylar fracture Dislocation +*

months, with a probable maximum at approximately 12 months after the fracture. Between 22 and 30 months after the trauma, a slight tendency for comparatively more rapid growth appears in the control bone, but this phenomenon is not statistically guaranteed at any time. Although such growth retardation, real or relative is registered in 11 cases — if 2 mm is accepted as proof of regress — a considerably larger material is needed to confirm the reality of such a phenomenon.

Fig 13 *Accumulated overgrowth in mm in humerus after supracondylar fracture Dislocation +*

Another observation with even less statistical foundation is a slight tendency to a second growth spurt occurring about 30 to 36 months after the fracture and noted in 6 cases. That such a doubtful observation is mentioned at all is explained by its occurrence in the other growth diagrams in this chapter and besides — actually with slight statistical significance —

Fig 14 Average overgrowth in mm during consecutive time intervals in humerus after supracondylar fracture Dislocation ++

in some of the growth curves in *Part Two* (cf p 00) Thus it cannot be excluded that this tendency to a second growth spurt unconvincing as yet does represent a reality where the physiological substratum is unknown

The existence of a tendency to growth retardation contributes to the value of accumulated average growth increase (Fig 13) being small 1.1 mm at the end of the 38th month Corresponding value after 18 months on the other hand is 3.3 mm (individual maximum value 7 mm) For more exact comparison with other fracture categories it would of course have been desirable to adjust the measuring values to the 40th month here too but the composition of the material did not allow this

4 Fract supracond humeri dislocation grade ++

The material consists of 33 cases of which 30 (90.9 %) show obvious growth acceleration Significant growth increase (Fig 14) can be established

Fig 15 Accumulated overgrowth in mm in humerus after supracondylar fracture Dislocation ++

approximately 8 months after the fracture and is maintained to the 21st month, with a probable maximum in the interval 16—18 months. Even 2 years or more after the injury, the curve still lies above the χ axis, but without statistical significance, which can be interpreted as a slight tendency for continued growth acceleration up to 3 years after the trauma. The accumulated average increase in length in the fractured bone during the time 0—40 months amounts to a final value of 8.8 mm (individual maximum value 18 mm) (Fig. 15), thus very considerably more than in the previous category. A slight tendency to growth retardation — whether true or relative — in the fractured bone during the third year, such as was mentioned in the previous fracture category, could be registered in 8 cases but as before with no statistical significance. Its influence on the final accumulated overgrowth was accordingly practically nil. A second growth acceleration, equally insignificant, was observed in two cases.

B Other statistical analysis of the clinical material

Adjustment of a curve indicating growth of the control bone (for the time being regarded as representative of normal humerus growth) was made with the method of least squares where the material was arranged in intervals of 1 year and consideration given to the localization of the measuring occasions in each annual interval (Fig. 16). The almost parallel course of the dotted lines (giving a confidence interval of 95 %) in close relation to the control curve indicates good statistical reliability in the age interval 5—15 years.

Fig. 16 Growth of control of humerus

Attempts were also made to appraise whether different intensity in the growth acceleration exists in different ages. Because of the limited scope of the material it was here necessary to work with all the fracture types combined. Because an increase of a few mm in length in a 2 year old child can imply equally large or larger relative added growth than 1 cm in a 10 year old the total length of the bone has been taken into account at the

approximately 8 months after the fracture and is maintained to the 21st month, with a probable maximum in the interval 16—18 months. Even 7 years or more after the injury, the curve still lies above the x axis but without statistical significance, which can be interpreted as a slight tendency for continued growth acceleration up to 3 years after the trauma. The accumulated average increase in length in the fractured bone during the time 0—40 months amounts to a final value of 8.8 mm (individual maximum value 18 mm) (Fig. 15), thus very considerably more than in the previous category. A slight tendency to growth retardation — whether true or relative — in the fractured bone during the third year, such as was mentioned in the previous fracture category, could be registered in 8 cases but as before with no statistical significance. Its influence on the final accumulated overgrowth was accordingly practically nil. A second growth acceleration equally insignificant was observed in two cases.

CHAPTER V

DISCUSSION

Faced with a compilation and evaluation of the results we may now recapitulate the original problems and the present standpoint of growth studies for which the reader is referred to pp 10 and 22. Here the problems posed by the author are surveyed point by point.

1 Is growth stimulus after fracture in long bone a constant phenomenon?

A question of this nature concerning measurements — comparatively good but none the less of limited accuracy — of biological material can not be expected to be given a 100 % positive answer. It is important here to determine when overgrowth is considered to occur and this is a matter that must be set in relation to method and method error. The question is also whether the problem is to be viewed from a strictly theoretical or a clinical aspect. If the problem is regarded practically clinically which is the case here mm accuracy is enough and thus the measurement method used is satisfactory.

It might now be objected that differences in length between the upper arms are of no practical importance and that a clinical view of this phenomenon is meaningless. As opposed to this however it can be said that the results obtained for humerus could in principle be applied to both femur and tibia in which difference in bone length is a real clinical problem.

To return to the above stated problem and with reference to figures for substantial overgrowth (>2 mm) given in the previous chapter it can be established that 70 out of the 86 cases in the material showed such an increase in growth i.e. 81 %. From a clinical standpoint this result at a general application would mean that measurable difference in bone length after fracture in growing long bone cannot be expected in every instance although most often and that the frequency of this — according to this material to the method used here and limited to humerus — lies around 80 %. It is not altogether certain that conclusions concerning growth in other long bones can be drawn from the results of this investigation particularly not if essential anatomical and/or physiological differences exist.

calculations. The investigation was made with covariance analysis and division into both 3 and 2 age groups was tried, but in no instance did it give significant differences.

The total fracture material was compiled in a diagram (Fig. 17) analogous to those made for the various fracture types. Such a compilation must,

Fig. 17. Average overgrowth in mm during consecutive time intervals in humeri estimated for the whole present fracture material and both degrees of dislocation.

of course, be taken with considerable reservation. The development of the growth stimulus records largely with that indicated for the separate fracture types, but the significance is higher during the period 8—21 months (cf. Table 4). Although statistically insignificant, the development of two humps in the growth diagram is slightly more pronounced here.

CHAPTER V

DISCUSSION

Faced with a compilation and evaluation of the results we may now recapitulate the original problems and the present standpoint of growth studies for which the reader is referred to pp 10 and 22. Here the problems posed by the author are surveyed point by point.

1 Is growth stimulus after fracture in long bone a constant phenomenon?

A question of this nature concerning measurements — comparatively good but none the less of limited accuracy — of biological material can not be expected to be given a 100 % positive answer. It is important here to determine when overgrowth is considered to occur and this is a matter that must be set in relation to method and method error. The question is also whether the problem is to be viewed from a strictly theoretical or a clinical aspect. If the problem is regarded practically clinically which is the case here mm accuracy is enough and thus the measurement method used is satisfactory.

It might now be objected that differences in length between the upper arms are of no practical importance and that a clinical view of this phenomenon is meaningless. As opposed to this however it can be said that the results obtained for humerus could in principle be applied to both femur and tibia in which difference in bone length is a real clinical problem.

To return to the above stated problem and with reference to figures for substantial overgrowth (>2 mm) given in the previous chapter it can be established that 70 out of the 86 cases in the material showed such an increase in growth i.e. 81 %. From a clinical standpoint this result at a general application would mean that measurable difference in bone length after fracture in growing long bone cannot be expected in every instance although most often and that the frequency of this — according to this material to the method used here and limited to humerus — lies around 80 %. It is not altogether certain that conclusions concerning growth in other long bones can be drawn from the results of this investigation particularly not if essential anatomical and/or physiological differences exist.

between humerus and such bones. Factors of special importance in this connexion might be circulatory conditions, arrangement of growth plates, normal growth curve for the bone in question, &c. Although no fundamental differences of this kind exist between different long bones, these reservations none the less suggest that on purely logical bases it is not justified to conclude that all long bones must show overgrowth in approximately the same frequency. Clinical experience, such as has been given by the authors mentioned in the historical account, suggests that overgrowth most often occurs in femur and next in tibia. *Calati & Poli* (1959) estimate the frequency of obvious growth stimulus at diaphysis fracture in femur to be 63.6 % in tibia 60 %, in humerus 27.7 %, and radius + ulna 14.3 %. These authors point out, however, that the real frequency figures are probably higher. The relation between the figures for the various long bones must also be questioned: that femur thus has a growth acceleration frequency more than twice as high as humerus ought in all probability to be reflected in some essential difference in the construction of these two bones, and this cannot possibly be. However, the fact that femur normally has a higher growth rate than humerus can have played some role in this connexion.

But if we accept the information from the above mentioned authors that femur and tibia fractures more often than humerus fractures are accompanied by increase in growth, and if the frequency of growth acceleration in humerus in accordance with the present author's results is approximately 80 %, it would suggest that fractures in the lower extremities almost always result in overgrowth. Here a factor enters through which the fractures of the bones are not directly comparable. It must be taken into account that investigations made so far of the growth stimulus concerning femur and tibia almost exclusively referred to diaphyseal fractures, which at least in the matter of femur often show considerable dislocation with accompanying larger periosteal lesion, haematoma formation, &c.

2 a Does the growth stimulus vary with the dislocation grade of the fracture?

As already mentioned *Barfod & Christensen* (1958) and *Hjort Guldhammer* (1963) noted especially strong increase in growth after severely dislocated fractures. *Blount* (1944, 1950, 1954), *Blomquist & Rudstrom* (1943) and others point out that operated fractures (which initially must usually have been considerably dislocated and where moreover the operation trauma results in further periosteal lesion, haematoma formation, &c.) are followed as a rule by strong overgrowth. *Leander* (1929) and others

on the other hand have not found any obvious relation between growth increase and dislocation. Most investigators in recent years have thus found that in this respect there is a positive correlation.

In the present author's material statistical significance exists concerning the difference in overgrowth between categories 3 and 4 p. 47 (supra condylar fractures dislocation grade + and ++)¹. The values for average accumulated overgrowth are most marked after 40 months: 11 mm for category 3, 8.8 mm for category 4. The investigation of the development of growth increase with respect to time (diagram 1 and 5) shows an obvious difference with values that are almost significant in category 3 and highly significant in category 4. It must thus be considered certain that moderately or severely dislocated supracondylar humerus fractures show an essentially higher growth acceleration than do non dislocated for which however there is a statistically verified growth increase although only slight.

Even though corresponding appraisal of the factors in diaphyseal and surgical neck fractures cannot be given statistical significance it must none the less be pointed out that of 8 and of 15 cases respectively with marked added growth only 2 belong to dislocation grade +. Here too a similar tendency can be discerned regarding the importance of the dislocation in these fracture types to what has just been said about the supracondylar fractures.

The present investigation does not explain or even indicate what causes this difference in growth reaction. A larger dislocation implies a greater vessel lesion, periosteal lesion, injury to soft parts, consequently a more intense reaction from surrounding tissues and a longer period of repair but which of these factors plays the decisive role here is an open question. That the positive correlation between dislocation and overgrowth must generally refer to all long bones seems to be beyond doubt. This factor has — with a high degree of probability — been shown partly to apply to three fracture types in one and the same bone and partly to agree with several clinical and scientific reports concerning femur and tibia (in *et al* Blount 1954, Barfod & Christensen 1958, Calati & Poli 1959, Goff 1960, Hjort Guldhammer 1963).

From what is mentioned above it now seems understandable that the femur diaphysis fractures which are most often severely dislocated and with overlapping ends practically always produce an increase in growth.

¹ Observed value of the test function $\chi^2 = 3.63$ 21 degrees of freedom

between humerus and such bones. Factors of special importance in this connexion might be circulatory conditions, arrangement of growth plates, normal growth curve for the bone in question &c. Although no fundamental differences of this kind exist between different long bones, these reservations none the less suggest that on purely logical bases it is not justified to conclude that all long bones must show overgrowth in approximately the same frequency. Clinical experience, such as has been given by the authors mentioned in the historical account, suggests that overgrowth most often occurs in femur and next in tibia. *Calati & Poli* (1959) estimate the frequency of obvious growth stimulus at diaphysis fracture in femur to be 63.6 % in tibia 60 % in humerus 27.7 %, and radius + ulna 14.3 %. These authors point out, however, that the real frequency figures are probably higher. The relation between the figures for the various long bones must also be questioned: that femur thus has a growth acceleration frequency more than twice as high as humerus ought in all probability to be reflected in some essential difference in the construction of these two bones, and this cannot possibly be. However, the fact that femur normally has a higher growth rate than humerus can have played some role in this connexion.

But if we accept the information from the above-mentioned authors that femur and tibia fractures more often than humerus fractures are accompanied by increase in growth, and if the frequency of growth acceleration in humerus in accordance with the present author's results is approximately 80 %, it would suggest that fractures in the lower extremities almost always result in overgrowth. Here a factor enters through which the fractures of the bones are not directly comparable. It must be taken into account that investigations made so far of the growth stimulus concerning femur and tibia almost exclusively referred to diaphyseal fractures, which at least in the matter of femur often show considerable dislocation with accompanying, larger periosteal lesion, haematoma formation, &c.

2 a Does the growth stimulus vary with the dislocation grade of the fracture?

As already mentioned *Barfod & Christensen* (1958) and *Hjort Guldhammer* (1963) noted especially strong increase in growth after severely dislocated fractures. *Blount* (1944, 1950, 1954), *Blomquist & Rudstrom* (1943) and others point out that operated fractures (which initially must usually have been considerably dislocated and where moreover the operation trauma results in further periosteal lesion, haematoma formation &c) are followed as a rule by strong overgrowth. *Lezander* (1929) and others

supracondylar fractures which however is outweighed by some cases with slight or no growth acceleration

ad β) As already explained in Chapter III there was no practical possibility of solving this problem by inserting an indicator in the diaphysis as a fixed measuring point. Measurements of patients around puberty during the years immediately before and after the disappearance of the distal growth plate were too few to allow even a rough estimate. Otherwise this is a time when at first two and later only one growth plate is in function from a large material of this age it could be possible to gain some information about this problem

2 c Does the growth stimulus vary with age?

A comparatively large increase in growth in children up to 4 years of age was observed by *Blomquist & Rudstrom* (1943) whereas *Barfod & Christensen* (1958) *Hjort Guldhammer* (1963) *Murayama* (1963) and to some extent also *Hedberg* (1944) hold that overgrowth is scanty during the 3—4 first years of life. Actual statistical significance in support of one or other view was not produced by these authors

No positive significant difference between different age groups was found in the present author's investigation irrespective of whether the material was distributed into 2 or 3 categories. It must be pointed out that the increase in growth at this analysis was not calculated in absolute figures but as a percentage of the bone length. Earlier investigators on the other hand have employed absolute figures (*Hedberg* 1944 *Barfod & Christensen* 1958 *Hjort Guldhammer* 1963)

Not only the size of the growth stimulus but also its duration in various ages could be valuable to investigate. With regard to the fact that the fracture healing process runs its course more rapidly during the first years of childhood and that the growth stimulus has been thought to continue as long as the consolidation of the fracture and the final reconstruction of the fractured bone are in progress (*Ollier* 1867 *Truea* 1953 *Goff* 1960 and others) it would be reasonable to find a shorter duration for overgrowth after fracture during the first years of life. It is possible that the growth acceleration is more rapid in the youngest but acts for a shorter period

Fig. 16 (growth of the control bone) which is supposed to show normal growth of the humerus (the implicit reservation is induced by observations in Part Two concerning growth disturbance in the control bone cf p. 90) and in any case is not likely to deviate much from the

whereas the humerus fractures with highly varied position and dislocation grade produce a lower frequency of overgrowth

2 b Does the growth stimulus vary with the distance of the fractures from the growth regions?

In chapter I (p 13) is stated that the growth potential is 3—4 times higher within the proximal humeral growth plate than in the distal plate. It may now be reasonable to assume that a fracture close to the growth plate with the higher potential has a different growth stimulating effect than a fracture just midway between the growth plates or one close to the plate where growth normally is slower. To estimate this not merely measurements of the development of the total humeral length but also ascertaining of the growth increments from each cartilage plate should be of importance. Accordingly, question 2 b becomes subdivided in two parts, namely

- α) Does the total overgrowth vary with the site of the fracture?
- β) How do the two growth plates of humerus react upon fractures at different levels?

ad α) From the previous part of the discussion it is clear that the degree of dislocation is an important factor when considering overgrowth. Thus, it is here necessary to compare only fractures with similar amount of displacement. It is a truism to state that this is difficult. What two fractures have the same displacement? Nevertheless in the categories 1 and 2 on pp 47—48 fractures of dislocation degree ++ are separated — and their average final growth given — while category 4 p 50, solely consists of such cases. With due reservation a comparison may be attempted. It then appears that average final overgrowth amounts to

in diaphyseal fractures, dislocation ++	7 mm
in fractures of the surgical neck, dislocation ++	9 mm
in supracondylar fractures dislocation ++	9 mm

From these values reliable conclusions are not to be drawn. The difference appearing between on the one hand metaphyseal, on the other diaphyseal fractures is definitely insignificant esp considering the small numbers for the shaft fractures. If the individual cases are scrutinized there may be noted a small preponderance for strong overgrowth (>10 mm) among the

supracondylar fractures which however is outweighed by some cases with slight or no growth acceleration

ad β) As already explained in Chapter III there was no practical possibility of solving this problem by inserting an indicator in the diaphysis as a fixed measuring point. Measurements of patients around puberty during the years immediately before and after the disappearance of the distal growth plate were too few to allow even a rough estimate. Otherwise this is a time when at first two and later only one growth plate is in function from a large material of this age it could be possible to gain some information about this problem

2 c Does the growth stimulus vary with age?

A comparatively large increase in growth in children up to 4 years of age was observed by *Blomquist & Rudstrom* (1943) whereas *Barfod & Christensen* (1958) *Hjort Guldhammer* (1963) *Murayama* (1963) and to some extent also *Hedberg* (1944) hold that overgrowth is scanty during the 3—4 first years of life. Actual statistical significance in support of one or other view was not produced by these authors

No positive significant difference between different age groups was found in the present author's investigation irrespective of whether the material was distributed into 2 or 3 categories. It must be pointed out that the increase in growth at this analysis was not calculated in absolute figures but as a percentage of the bone length. Earlier investigators on the other hand have employed absolute figures (*Hedberg* 1944 *Barfod & Christensen* 1958 *Hjort Guldhammer* 1963)

Not only the size of the growth stimulus but also its duration in various ages could be valuable to investigate. With regard to the fact that the fracture healing process runs its course more rapidly during the first years of childhood and that the growth stimulus has been thought to continue as long as the consolidation of the fracture and the final reconstruction of the fractured bone are in progress (*Ollier* 1867 *Trueta* 1953 *Goff* 1960 and others) it would be reasonable to find a shorter duration for overgrowth after fracture during the first years of life. It is possible that the growth acceleration is more rapid in the youngest but acts for a shorter period.

Fig. 16 (growth of the control bone) which is supposed to show normal growth of the humerus (the implicit reservation is induced by observations in *Part Two* concerning growth disturbance in the control bone cf p. 90) and in any case is not likely to deviate much from the

normal curve, shows that the growth more or less runs its course not far from linearly between the ages of 4 and 15 years. This could support to some extent the concept held by *Blount* and others that the growth stimulus after fracture varies little in the mentioned age interval.

At investigation of the importance of the age factor, the skeletal age should by rights be determined and used as basis for the appraisal Röntgenological material (pictures of hand skeleton) for such calculations; however, was not available to the author. The developmental level of the bone nuclei in both ends of humerus provides no basis for sufficiently accurate determination of skeletal age.

3 How soon after fracture can growth stimulus be demonstrated, and when does it terminate?

As explained in the previous chapter, it was not possible to give the exact time for the appearance of measurable growth increase. The earliest recording that can be allotted any statistical significance refers to the fractures in the surgical neck and was made within approximately 4 months after the injury. The progress before that is not sufficiently mapped to allow any statement whatsoever.

Observation of the curves for the growth acceleration in relation to the number of months since the injury (see Fig. 10, 12, 14) gives an indication of the time for the maximum increase in growth. This maximum is most pronounced for the supracondylar fractures of dislocation grade ++, where it occurs 16—18 months after the injury. Its appearance is more vague in supracondylar fractures of dislocation grade + where it occurs 12 months after the injury, and in *collum chirurgicum* fractures where the interval is 12—16 months. With reservation for the fact that nothing is known about the growth acceleration during the first 4 months it can thus be maintained that a maximum occurs 12—18 months after the fracture. This phenomenon does not appear to have been accurately recorded earlier. To what extent it coincides with any phase in the consolidation of the fracture or in the vascular post-traumatic reaction is a problem not contained in this investigation.

The termination of statistically significant increase in growth for dislocated supracondylar fractures occurs at 21 months; for non-dislocated fractures at 14 months; and for *collum chirurgicum* fractures approximately 16 months after the injury. The curves, however, do not reach zero position at the mentioned times. For the first mentioned fractures the average values of increase in growth lie somewhat above the x-axis until

fully 36 months after the injury, and almost the same condition applies to the *collum chirurgicum* fractures. This might be interpreted as a limited tendency to persistent overgrowth in the fractured bone.

Contrary to this the curve for non dislocated supracondylar fractures intersects the x axis at 20 months and thereafter shows for at least one year a slight tendency to negative values in other words a higher growth rate for the control side whether this is due to acceleration of the growth in uninjured bone or to retardation in fractured bone. These statistically not guaranteed slightly negative values for average growth per time interval partly condition the insignificant accumulated growth of the non dislocated supracondylar fractures. At the time when the curve goes below the x axis the average total growth is 3.5 mm but thereafter slowly reduces to the final value 1.1 mm mentioned before.

No doubt there is a similarity between the diagrams for the development of growth acceleration in dislocated supracondylar fractures and fractures through the surgical neck while the corresponding curve for non dislocated supracondylar fractures is not only flatter but also remains on the positive side for a much shorter time. In what other respect then are the two first mentioned fracture categories mutually comparable and different from the lastmentioned group? It seems probable that the dislocation grade plays a role here too. Of the 18 fractures through the surgical neck 11 belong to grade ++ i.e. 61 %. This relative majority for dislocated fractures might be reflected in a development of the growth acceleration similar to that in dislocated supracondylar fractures. Hypothetically and with emphasis on the fact that the parts of the curves which lie beyond 18—20 months lack statistical significance it could be postulated that the duration of growth stimulation is correlated to the amount of dislocation. This appears to be a justifiable statement because there is reason to suppose that the reparative processes in the bone require far longer time after a severely dislocated fracture than after a fracture in exact position and this remodelling is generally assumed to concur with the process of overgrowth. Already Ollier (1867) thought that the reopening of the medullary cavity would coincide with the disappearance of the growth stimulus a theory which Trueta (1953) has emphasized. The so-called medullization must obviously be a much slower process when the fracture ends are widely displaced or overriding than when the contact is close.

4 *Are there signs of equalization of bone length difference produced by fracture during the continued course of growth?*

Individual observers have noted a more or less pronounced tendency to equalization of post traumatic bone length difference. *L. Bohler* (1924) states that these length discrepancies are transient. *M. Brattstrom* (1963) who investigated children with rheumatoid gonarthrosis, found with roentgenological measurements a moderate increase in growth on the diseased side, which was eliminated, however, during the course of one or two years.

The only factor in the present material that might argue for a regress in part of the overgrowth is the statistically nonsignificant negative values of increase in growth 2—3 years after non-dislocated supracondylar fracture. In some isolated cases of dislocated supracondylar fractures similar observations were also made. This highly uncertain observation is hard to explain, especially as it cannot be determined whether it is a question of retardation of the fractured bone or of acceleration of the control bone. In the case of mechanical traumata, *Blount* (1954) has found that the growth plate nearest to the fracture ceases to function somewhat earlier than normally which probably argues for a lower growth rate during the immediately previous period. This can to some extent (fracture cases near the puberty) be the cause of the mentioned uncertain negative growth values 2—3 years after a fracture.

PART TWO

Experimental Study of Growth Reactions from Proximal and Distal Growth Regions After Cortical Drilling

4 Are there signs of equalization of bone length difference produced by fracture during the continued course of growth?

Individual observers have noted a more or less pronounced tendency to equalization of post traumatic bone length difference *L. Bohler* (1954) states that these length discrepancies are transient *M. Brattstrom* (1963) who investigated children with rheumatoid gonarthrosis, found with roentgenological measurements a moderate increase in growth on the diseased side which was eliminated, however during the course of one or two years

The only factor in the present material that might argue for a regress in part of the overgrowth is the statistically nonsignificant negative values of increase in growth 2—3 years after non dislocated supracondylar fracture. In some isolated cases of dislocated supracondylar fractures similar observations were also made. This highly uncertain observation is hard to explain, especially as it cannot be determined whether it is a question of retardation of the fractured bone or of acceleration of the control bone. In the case of mechanical traumata, *Blount* (1954) has found that the growth plate nearest to the fracture ceases to function somewhat earlier than normally which probably argues for a lower growth rate during the immediately previous period. This can to some extent (fracture cases near the puberty) be the cause of the mentioned uncertain negative growth values 2—3 years after a fracture.

CHAPTER VI

STIMULATION OF LONGITUDINAL BONE GROWTH BY EXPERIMENTAL TRAUMA REVIEW OF LITERATURE

The various operations that are performed clinically to increase the longitudinal growth locally in a bone have most often been tested before hand on experimental animals mostly rabbit therefore a copious literature exists in which the effects of various forms of trauma to bone tissue and periosteum have been investigated in animals. A variant of this the placing of different organic or inorganic substances in the medullary cavity or metaphysis however is only indirectly related to the theme of this investigation (cf *Langenbeck* 1869 *Meisenbach* 1910 *Kor gswieser* 1925 *Trout* 1915 *Bohlman* 1929 *Bergmann* 1931 *Kishikawa* 1936 *Wu & Miltner* 1937 *Chapchal & Zeldenrust* 1948 *Bertrand & Trillat* 1948 *Pease* 1952 *Wilson & Percy* 1956 *Haas* 1958 *Nordentoft & Guldhammer* 1964 and others). For placing the various materials in the bone some form of fenestration or drilling through periosteum and cortex is of course required and the reports do not allow any positive judgement whether the recorded often insignificant or inconstant increases in growth are due to traumatization of bone (periosteum) or to the presence of a foreign body or to both. Because these experiments are not purely traumatic they are left out here.

A Periosteal strippings

O'lier (1867) removed the periosteum from the tibia diaphysis in a series of rabbits. Three months later he could record an elongation of the operated bone of 2—5 mm. Similar experiments do not appear to have taken place until *Wu & Miltner* (1937) reported a series of stimulation experiments on 22 rabbits which included periosteal stripping of varying extent. During the course of 3 months 19 of the 22 developed a considerable overgrowth in the operated bone of from 5—15 % of the total length. The experiments were repeated by *Lacroix* (1951) who obtained a clear reaction in 7 out of

PART TWO

INTRODUCTION

With clinical material and roentgenological investigation, the first part of this work has provided much information of a high degree of probability concerning growth stimulation in various types of fractures in *homo* and the information obtained has satisfactorily answered most of the problems. When the experiments with insertion of diaphyseal metal indicator were abandoned (p 43), it was impossible to determine the relative growth proportion from proximal and distal growth region after fracture, and because of the limited material, it was also impossible to judge whether different fracture level gave different growth stimulus (problem 2 b p 000). With the object of gaining better information on this point an experimental investigation was added where traumatization of long bone in growing rabbits was carried out. The investigation method in the present part is in many respects based on a work published by Hansson (1967) *Daily Growth in Length of Diaphysis Measured by Oxytetracycline in Rabbit*. Thus the same intravital labelling method and the same preparation technique was used and the fluorescence microscopical investigation was made with the same optical equipment. For this reason the description in some sections could be given summarily and for complementing details the reader is referred to the very detailed work just mentioned.

B Drilling through the metaphyseal cortex into the medullary cavity

As mentioned earlier, metaphyseal drilling was tested clinically by *Ferguson* (1933) and the report of it probably induced *Kishikawa* in 1936 to perform similar drillings in an unknown number of rabbits. A few weeks later he could establish roentgenologically growth increase in most of the experimental animals. *Compere & Adams* in 1937 continued along the same lines and drilled holes in the femur of rabbits in the two metaphyses as well as in the centre of the diaphysis in one and the same bone. Ten weeks later no measurable increase in length could be established. However only 6 experimental animals were used. *Hutchison & Burdeaux* (1954) besides stasis experiments also performed drillings out of 10 dogs. 5 showed overgrowth.

Common to the stimulus experiments mentioned here is that the number of the experimental animals was too small that the measuring method was hardly precise enough and that the localization of the drillings was not reported with any degree of accuracy. *Hansson & Wiberg* (1963) and *Wiberg* (1964) used drilling more systematically and in larger series. In an experimental series where 16 rabbits were used drilling was carried out with dental drill (diameter 2 mm) both in the distal femur epiphysis and in the proximal tibia metaphysis. In two other series of 17 and 14 rabbits respectively drilling was performed in the proximal tibia metaphysis only. During the following period of 2 months the animals were sacrificed and the length of tibia was determined with the aid of 0.1 mm—graduated calipers. A growth increase of up to 1.0 mm was recorded in all series. The experiments however were mainly intended to discover possible post-traumatic reaction in the proximal growth cartilage of the tibia which was studied microscopically in all experimental animals. The number of cells in the cell columns of the proliferative zone were found to decrease during the days immediately after the drilling and the whole of this zone reduced in height as did the entire growth cartilage. In general no definite changes could be found in the hypertrophic layer. However this investigation did not permit any positive conclusions concerning whether this reduction of the growth cartilage was related to increased or retarded growth rate because the recording of the growth referred to the total growth increase of tibia.

8 animals, and at about the same time, *Voutey* (1948) and *Bertrand & Tralat* (1948) reported similar results

The importance of local blood supply for longitudinal growth was investigated in rabbit by *Brodin* (1955). He performed periosteal stripping in the proximal half of tibia (saving a *nutritia*), placed a metal indium in the diaphysis, and followed roentgenologically the continued growth. This showed unchanged normal growth from the proximal plate, but a clearly increased growth from the distal plate. *Langenskiöld* (1957) supplemented stripping with an application of plastic film around the diaphysis, which also resulted in overgrowth. *Elo* (1960) used a similar procedure but instead, inserted a skin graft subperiosteally in the proximal metaphyseal region of tibia and could, during the following weeks, record a growth increase, mainly caused by increased activity from the distal growth plate. *Solá et al* (1963) judged periosteal stripping to be a fairly effective method for producing overgrowth. Their article is otherwise concerned with the effect of iterated stripping which, however, did not result in any further growth increase. This was also established by *Wu & Miltner* (1937).

B Drilling through the metaphyseal cortex into the medullary cavity

As mentioned earlier, metaphyseal drilling was tested clinically by *Ferguson* (1933) and the report of it probably induced *Kishikawa* in 1936 to perform similar drillings in an unknown number of rabbits. A few weeks later he could establish roentgenologically growth increase in most of the experimental animals. *Compere & Adams* in 1937 continued along the same lines and drilled holes in the femur of rabbits in the two metaphyses as well as in the centre of the diaphysis in one and the same bone. Ten weeks later no measurable increase in length could be established. However only 6 experimental animals were used. *Hutchison & Burdeaux* (1954) besides stasis experiments also performed drillings: out of 10 dogs, 5 showed overgrowth.

Common to the stimulus experiments mentioned here is that the number of the experimental animals was too small that the measuring method was hardly precise enough and that the localization of the drillings was not reported with any degree of accuracy. *Hansson & Wiberg* (1963) and *Wiberg* (1964) used drilling more systematically and in larger series. In an experimental series where 16 rabbits were used drilling was carried out with dental drill (diameter 2 mm) both in the distal femur epiphysis and in the proximal tibia metaphysis. In two other series of 17 and 14 rabbits respectively drilling was performed in the proximal tibia metaphysis only. During the following period of 2 months the animals were sacrificed and the length of tibia was determined with the aid of 0.1 mm—graduated calipers. A growth increase of up to 10 mm was recorded in all series. The experiments however were mainly intended to discover possible post-traumatic reaction in the proximal growth cartilage of the tibia which was studied microscopically in all experimental animals. The number of cells in the cell columns of the proliferative zone were found to decrease during the days immediately after the drilling and the whole of this zone reduced in height as did the entire growth cartilage. In general, no definite changes could be found in the hypertrophic layer. However this investigation did not permit any positive conclusions concerning whether this reduction of the growth cartilage was related to increased or retarded growth rate because the recording of the growth referred to the total growth increase of tibia.

8 animals, and at about the same time, *Vontey* (1948) and *Bertrand & Trlat* (1948) reported similar results

The importance of local blood supply for longitudinal growth was investigated in rabbit by *Brodin* (1955). He performed periosteal stripping in the proximal half of tibia (saying a *nutritia*) placed a metal indicator in the diaphysis, and followed roentgenologically the continued growth. It showed unchanged normal growth from the proximal plate but a clearly increased growth from the distal plate. *Langenskiöld* (1957) supplemented stripping with an application of plastic film around the diaphysis which also resulted in overgrowth. *Elo* (1960) used a similar procedure but, instead, inserted a skin graft subperiosteally in the proximal metaphyseal region of tibia and could, during the following weeks, record a growth increase, mainly caused by increased activity from the distal growth plate. *Sola et al* (1963) judged periosteal stripping to be a fairly effective method for producing overgrowth. Their article is otherwise concerned with the effect of iterated stripping which, however, did not result in any further growth increase. This was also established by *Wu & Miltner* (1937).

C Experimental fractures and osteotomies

Growth studies made with the aid of experimental fractures and osteotomies are reported frequently in the literature. One of the earliest was made by *Leander* (1929). During his clinical investigations he had, as mentioned (p. 17), observed that increase in length of tibia could occur after femur fracture, which was investigated in closer detail experimentally with roentgenological measuring technique. *Leander* began by investigating anamelia in rabbits but could not demonstrate any of importance. Thereafter 13 artificial fractures of tibia were described. In 11 of these experimental animals *Leander* could prove increase in length of femur. Moreover 5 femur fractures were also made and here positive increase in length in tibia was found in 1 rabbit and uncertain increase in 3. The reaction of femur to tibia fracture was observed to be considerably stronger than reaction of tibia to femur fracture. *Leander* also noted that the increased growth reaches a certain maximum and is then inclined to slow down. The author did not mention precisely where the fractures were situated. However, they were made with percutaneous breaking in the middle of the diaphyses. In 1936 *Bisgard* and in 1937 *Bisgard & Martenson* reported experiments carried out with goats. Diaphyseal fractures were made and then controlled with repeated roentgenological measurements. The fractures were transverse with or without overriding position and in both cases resulted in small growth increase of a few mm.

Compere & Adams in 1937 published several different series of experiments with growth stimulus including diaphysis fractures among others. These had actually been made with the object of finding out positively — with the aid of them and of indicators placed on each side of the fracture — whether interstitial growth occurs at healing. No such growth could be demonstrated in rabbit but increased longitudinal growth was noted as secondary finding in fibula at fracture of tibia, a phenomenon attributed to the regional post-traumatic hyperaemia. The authors, who also experimented by drilling holes as well as with complete fractures, found that the former, as distinct from the fractures, gave no measurable growth increase. They therefore presumed that dislocation could be of importance for the development of overgrowth.

Greille & Janes in 1937 published a report of experimental fractures in puppies where growth increase was accounted for in all instances. This

A similar experimental trauma was used by *Hansson* (1967) in his investigation of the growth in rabbit tibia after different types of skeletal trauma. Here, too, drilling was performed, but the hole was made about 5 mm in diameter and was located 8—10 mm below the proximal growth plate of tibia. With this type of drilling, intentional destruction of the medulla, level with the drilled hole, was also made with the aid of the drill. Plugging was then carried out with homologous bone, as earlier suggested by *Trueta* (1953, 1958) and used clinically by among others *Stahl* (1957). This so called plugging is done by picking the medullary cavity level with the drill hole with homologous bone, whereby the vascular branches from a *nutritia* are expected to be completely destroyed. Growth determinations were then made with tetracycline technique (for details, see below). These determinations showed that traumatizations of the type described here resulted in slight stimulus in the proximal growth plate and a considerably more powerful stimulus in the distal in the operated long bone, compared with the contralateral. Similar reaction was obtained after drilling with medullary cavity destruction, but without plugging, whereas merely drilling and avoiding medullary lesion resulted in about the same growth stimulus in the two growth cartilages in the operated bone. The stimulus in the proximal growth region, whose medullary vessels were in this case intact, was thus more pronounced than after the previously mentioned operations. Corresponding reaction was found to a lesser degree also at only periosteal incision.

C Experimental fractures and osteotomies

Growth studies made with the aid of experimental fractures and osteotomies are reported frequently in the literature. One of the earliest was made by *Letander* (1929). During his clinical investigations he had as mentioned (p. 17) observed that increase in length of tibia could occur after femur fracture which was investigated in closer detail experimentally with rontgenological measuring technique. *Letander* began by investigating anisomelia in rabbits but could not demonstrate any of importance. Thereafter 13 artificial fractures of tibia were described. In 11 of these experimental animals *Letander* could prove increase in length of femur. Moreover 5 femur fractures were also made and here positive increase in length in tibia was found in 1 rabbit and uncertain increase in 3. The reaction of femur to tibia fracture was observed to be considerably stronger than reaction of tibia to femur fracture. *Letander* also noted that the increased growth reaches a certain maximum and is then inclined to slow down. The author did not mention precisely where the fractures were situated. However they were made with percutaneous breaking in the middle of the diaphyses. In 1936 *Bisgard* and in 1937 *Bisgard & Martenson* reported experiments carried out with goats. Diaphyseal fractures were made and then controlled with repeated rontgenological measurements. The fractures were transverse with or without over riding position and in both cases resulted in small growth increase of a few mm.

Compere & Adams in 1937 published several different series of experiments with growth stimulus including diaphysis fractures among others. These had actually been made with the object of finding out positively — with the aid of them and of indicators placed on each side of the fracture — whether interstitial growth occurs at healing. No such growth could be demonstrated in rabbit but increased longitudinal growth was noted as secondary finding in fibula at fracture of tibia a phenomenon attributed to the regional post traumatic hyperaemia. The authors who also experimented by drilling holes as well as with complete fractures found that the former as distinct from the fractures gave no measurable growth increase. They therefore presumed that dislocation could be of importance for the development of overgrowth.

Greville & Jones in 1957 published a report of experimental fractures in puppies where growth increase was accounted for in all instances. This

series also seemed to provide evidence for the opinion that the growth acceleration was most marked where there was obvious dislocation. In Sweden, *Blomquist & Rudstrom* in 1943 carried out experiments that were fairly identical with those reported by *Compere & Adams* and obtained similar results. *Wray*, who with different co workers studied the vascular reaction to fracture at the end of the 1950s, showed together with *Goodman* in 1961 that it is possible at diaphysis fracture in rat tibia to establish a temporary halt to the growth in femur, not only on the same side but also in the contralateral extremity. This however, in a short time changes into accelerated growth bilaterally, although mostly on the fracture side. In 1965 *Yabsley & Harris* investigated the effect that closed fractures in rabbit tibia could have on the blood supply to the growth plate, and in passing, recorded an increase in length after these fractures.

To summarize the survey of the literature given here has shown that increase in growth is obtained both after periosteal stripping, after drilling the medullary cavity, and after fracture (osteotomy). Bases have been found for the supposition that the extent of the growth acceleration is related to the degree of severity of the dislocation. It was observed more over that trauma to a long bone in an extremity can affect the growth rate in other bones in the same extremity.

Finally, some investigators have noted that a trauma in the vicinity of the proximal growth region of a long bone triggers off increased growth not appreciably from the adjoining growth plate, but from the distal

CHAPTER VII

MATERIAL

Most experimental growth studies seem to have been carried out on rabbit although chicken rat guinea pig pig goat dog have also been used (cf reviews by *Taillard & Morscher* 1965 *Hansson* 1967, *Sunden* 1967) The advantage of using rabbit is its rapid growth moreover its long bones contrary to rat and guinea pig are large enough to allow operative measures *Hansson* (1967) developed a method for exact growth determination and mapped the normal growth in rabbit it therefore seemed fitting to use rabbits for this part of the present author's studies

Litters of white rabbits supplied from two different sources were used They were aged about 4 weeks when delivered without mother to the animal depot Thereafter they were observed for some days before the experiments were performed The weight of those that seemed healthy varied from 300 to 600 gm at the beginning of the experimental period i.e. aged approximately 30 days They were fed with vitaminized nutritive preparations in the form of pellets (Ewos) and water They were housed in cages made of wire-netting with floors of the same material in a room with daylight where the temperature was 16–18° C and the relative humidity 40–50 %

609 rabbits were used of which 205 were discarded for various reasons The largest loss was caused by unsuccessful preparations of sections for growth determinations the next by lethal enterocolitis and finally deaths occurred in connexion with the operations

Occasional instances of diarrhoea occurred probably caused by slight enterocolitis but as long as these symptoms had no obvious negative effect on the body weight of the animals (recorded both at the arrival and at frequent intervals during the experimental period) such a slight disorder was not considered sufficient to disqualify the animals (cf *Persson* 1968)

CHAPTER VIII

METHODS

A Notes on the choice of methods

At the start of the experimental studies, three questions were posed

- 1 What stimulation methods should be employed?
- 2 In which bones, and where on them, should the growth stimulating method be applied?
- 3 What measuring method should be used?

Ad 1) What was desired, was a fracture or a trauma as similar to a fracture as possible. Causing a fracture by breaking a long bone without exposing it was of course a simple measure (cf *Levander 1929, Compere & Adams 1937*), but it would not be possible to place it with desirable anatomical precision and the degree of dislocation and possible splintering could vary considerably. It could also be presumed that an experimental animal so treated would not put weight on the damaged bone (radius, however, is an exception, cf below) and the withdrawal of the pressure of the body weight could be expected to have some effect on the growth. Several studies (*Ollier 1867, Macewen 1912, Bergmann 1931, Compere & Adams 1937, Arkin & Katz 1956, Geiser 1957, Geiser & Trueta 1958, Ring 1961, Sunden 1967*) exist concerning the reaction of the longitudinal skeletal growth to nonloading or immobilization that have produced very varying results according to some growth stimulation according to others retardation. The above thus argues against deliberately fracturing as a suitable method.

The same objection can be raised against performing osteotomies. Here also appears considerable trauma of soft parts whose possible influence however could be eliminated by sham operations.

Drilling of the cortex could be said to represent a suitable form of trauma, at the same time as the experimental animal could be expected to load its damaged leg fairly normally. According to *Hansson (1967)* periosteal lesion alone of the size required here produces very slight growth reaction, whereas drilling restricted to the cortex as well as drilling through the cortex across the medullary cavity could be expected to produce more pronounced growth stimulation. The latter type of lesion could relatively well be compared to a fracture which in both diaphysis and metaphyses must usually result in destruction of medullary vessels. It

should not be difficult to drill in the exact place and in the matter of the medullary cavity it seemed to be technically simple to allow the drill to pass across it and be stopped by the opposite cortex

It thus seemed most suitable to choose drilling combined with medullary trauma

Ad 2) The clinical investigation was made on humerus. It was therefore logical to carry out the experimental study on this bone. Humerus in rabbit however is not particularly suitable for growth determination with the tetracycline method because the proximal growth plate on axial sections is visualized as wavy or corrugated (*Hansson* personal communication). This was judged disadvantageous for the exactness of the planned measurements. Humerus was therefore rejected as experimental object.

Tibia (tibio-fibula) is the long bone in rabbit that is most often used at different kinds of experimental studies. It is easily accessible anatomically, is large enough to allow various kinds of operations, and its two growth regions offer no special problems at preparing.

Another long bone whose qualities from experimental orthopaedic aspect can be considered favourable is radius. This bone is also easily accessible and its growth regions are easy to prepare. Moreover, ulna is able to bear the body weight and the extremity is thus not out of function after an operation on radius.

For these various reasons the author decided to use tibia and radius for his studies.

In the matter of placing the drill traumata the intention was to try to reproduce the three clinical fracture variants in humerus by drilling holes in both tibia and radius either proximally, metaphyseally, diaphyseally or distally metaphyseally. Concerning the metaphyseal drillings it was important not to produce lesion of the growth cartilage; it was therefore decided regarding tibia to place the drill centre about 5 mm from the nearest part of the growth plate. The drill was 2.3 mm diameter. In the case of radius it was necessary to use a thinner drill, diameter 1.6 mm, otherwise the trauma could destroy almost the whole of the bone's bulk. The diaphyseal drilling was made in both radius and tibia in the middle of the bone.

Ad 3) There were no particular doubts concerning the measuring method. The author's original purpose was to carry out determinations of the longitudinal growth by tetracycline labelling, which when the study was to begin was used by *Hansson* (1964, 1967) with success and compared with earlier measuring methods with an exactness never before attained.

B The tetracycline labelling method for the determination of the growth rate of long bones

After *Andres* (1956) discovery and *Milch et al s* (1957) more intensive study of the affinity of the tetracyclines to tissues during mineralization the various tetracyclines and perhaps especially oxytetracycline (OTC) have come into general use at the study of endochondral growth, lamellar bone formation, dentine and enamel formation (see, e.g., *Hultb & Olerud* 1962, *Urist & Ibsen* 1963, *Hansson* 1964, 1967, *Sunden* 1967, *Ahlgren* 1968, *Persson* 1968)

Although OTC is undoubtedly toxic, this can be ignored in the doses required for intravital labelling of bone (*Hansson* 1967), and investigations made so far seem to show that this substance is the least harmful in the tetracycline group (*Harris et al* 1962, *Olsen* 1963-1965, *Kienitz* (1965))

In agreement with *Hansson's* study of the OTC effect on the endochondral growth (1967) a dose of 10 mg/kg body weight was chosen. This was administered intravenously in a marginal ear vein. No signs of toxic effect in the form of deformed cartilaginous trabeculae in the growth region were observed with certainty at this dose. The OTC preparation employed was Terramycin® *ad us vet* (Pfizer).

Hansson's method (1964-1967) was used for the preparing. Thus the bones after being dissected out were fixed in absolute ethyl alcohol for 24-72 hours usually and preferably for 48 hours. Longitudinal sections were then cut in the frontal plane with a razor blade while observing parallelity with the metaphyseal bone trabeculae. The sections were placed for about 5 minutes in xylol and thereafter mounted in DePeX (Gurr London). The preparations were kept for 24 hours in a darkened room whereafter examination was made with fluorescence microscope.

The optic equipment consisted of a binocular Zeiss fluorescence microscope with a mercury lamp as source of light (Osram HBO 200 W) and a combination of primary filters BG 12/4 and BG 38/2.5, as well as barrier filter 47. A dark field condensor NA 0.65/0.85 was also used. A measuring ocular (Kpl 12.5 x) furnished with a 10 mm micrometer with 100 divisions was used, as well as a plane achromatic objective 10 x (NA 0.22). The system was calibrated with the aid of an objective micrometer (Reichert) so that every division on the scale corresponded to 10 microns.

C The timing of the investigation

Preliminary investigations showed that it was most suitable to carry out a 3 twenty-four hour study of the growth where the skeletal trauma would be applied at the beginning of the second 24 hour period and where OTC would be administered 4 times at the beginning of the first second and third 24 hour period and at the end of the third immediately before the animal was sacrificed. Thus four fluorescing OTC injection zones would be obtained (for measuring points see below). These are designated A B C and D in the following

- Distance A—B growth increase during the pre operative 24 hour period
= normal growth
- Distance B—C growth increase during the first postoperative 24 hour period
- Distance C—D growth increase during the second postoperative 24 hour period

Fig 18 Microphotograph of proximal tibial metaphysis from growing rabbit with the four fluorescing oxytetracycline zones mentioned on p

B The tetracycline labelling method for the determination of the growth rate of long bones

After André's (1956) discovery and Melchior *et al.* (1957) more intensive study of the affinity of the tetracyclines to tissues during mineralization, the various tetracyclines and perhaps especially oxytetracycline (OTC) have come into general use at the study of endochondral growth, lamellar bone formation, dentine and enamel formation (see, e.g., Hill & O'Brien 1962, Urist & Jaber 1963, Harsson 1964, 1967, Sander 1967, Ingber 1968, Persson 1968).

Although OTC is undoubtedly toxic, this can be ignored in the doses required for intravital labelling of bone (Harrison 1967) and investigations made so far seem to show that this substance is the least harmful in the tetracycline group (Harris *et al.* 1962, Ozer 1963, 1965, Kier *et al.* (1965)).

In agreement with Harrison's study of the OTC-effect on the endochondral growth (1967) a dose of 10 mg/kg body weight was chosen. This was administered intravenously in a marginal ear vein. No signs of toxic effect in the form of deformed cartilaginous trabeculae in the growth region were observed with certainty at this dose. The OTC preparation employed was *Tetracycline ad us re* (Pfizer).

Harrison's method (1964, 1967) was used for the preparation. Thus the bones after being dissected out were fixed in absolute ethyl alcohol for 24–72 hours usually and preferably for 48 hours. Longitudinal sections were then cut in the frontal plane with a razor blade, while observing parallelly with the metaphyseal bone trabeculae. The sections were placed for about 5 minutes in xylol and thereafter mounted in DePeX (Gurr, London). The preparations were kept for 24 hours in a darkened room whereafter examination was made with fluorescence microscope.

The optic equipment consisted of a binocular Zeiss fluorescence microscope, with a mercury lamp as source of light (Osram HBO 200 W) and a combination of primary filters BG 12 + and BG 38 2.5 as well as barrier filter 47. A dark field condensor NA 0.65 D 85 was also used. A measuring ocular (Hpl 12.5 x) furnished with a 10 mm micrometer with 100 divisions was used, as well as a plane achromatic objective 10 x (NA 0.22). The system was calibrated with the aid of an objective micrometer (Reichert) so that every division on the scale corresponded to 10 microns.

C The timing of the investigation

7 Preliminary investigations showed that it was most suitable to carry out a 3 twentyfour hour study of the growth where the skeletal trauma would be applied at the beginning of the second 24 hour period and where OTC would be administered 4 times at the beginning of the first second and third 24 hour period and at the end of the third immediately before the animal was sacrificed. Thus four fluorescein, OTC injection zones would be obtained (for measuring points see below). These are designated A B C and D in the following

Distance A—B growth increase during the pre operative 24 hour period
=normal growth

Distance B—C growth increase during the first postoperative 24 hour period

Distance C—D growth increase during the second postoperative 24 hour period

Fig 18 Microphotograph of proximal tibial metaphysis from growing rabbit with the four following oxytetracycline zones mentioned on p

B The tetracycline labelling method for the determination of the growth rate of long bones

After *Andres* (1956) discovery and *Milch et al's* (1957) more intensive study of the affinity of the tetracyclines to tissues during mineralization the various tetracyclines and perhaps especially oxytetracycline (OTC) have come into general use at the study of endochondral growth lamellar bone formation dentine and enamel formation (see, e.g. *Hulth & Olerud* 1962 *Urist & Ibsen* 1963, *Hansson* 1964, 1967 *Sunden* 1967, *Ahlgren* 1968 *Persson* 1968)

Although OTC is undoubtedly toxic, this can be ignored in the doses required for intravital labelling of bone (*Hansson* 1967) and investigations made so far seem to show that this substance is the least harmful in the tetracycline group (*Harris et al* 1962, *Owen* 1963 1965, *Kienitz* (1965)

In agreement with *Hansson's* study of the OTC-effect on the endochondral growth (1967) a dose of 10 mg/kg body weight was chosen. This was administered intravenously in a marginal ear vein. No signs of toxic effect in the form of deformed cartilaginous trabeculae in the growth region were observed with certainty at this dose. The OTC preparation employed was Terramycin® *ad us vet* (Pfizer)

Hansson's method (1964 1967) was used for the preparing. Thus the bones after being dissected out were fixed in absolute ethyl alcohol for 24—72 hours usually and preferably for 48 hours. Longitudinal sections were then cut in the frontal plane with a razor blade, while observing parallelity with the metaphyseal bone trabeculae. The sections were placed for about 5 minutes in xylol and thereafter mounted in DePeX (*Gurr*, London). The preparations were kept for 24 hours in a darkened room whereafter examination was made with fluorescence microscope.

The optic equipment consisted of a binocular *Zeiss* fluorescence microscope with a mercury lamp as source of light (*Osram* HBO 200 W) and a combination of primary filters BG 12/4 and BG 38/25 as well as barrier filter 47. A dark field condensor NA 0.65/0.85 was also used. A measuring ocular (Kpl 12.5x) furnished with a 10 mm micrometer with 100 divisions was used as well as a plane achromatic objective 10x (NA 0.22). The system was calibrated with the aid of an objective micrometer (*Reichert*) so that every division on the scale corresponded to 10 microns.

D Operation method

As described on p 72 the author chose to carry out proximal mid diaphyseal and distal drillings of tibia and radius (cf Fig 19 and 20)

The number of animals in each of the six categories is listed in the following table

Tibia proximal drilling	69
mid diaphyseal drilling	54
distal drilling	70
Radius proximal drilling	63
drilling	39
distal drilling	75
Sham operation tibia	6
radius	6
Narcosis alone	15
No measure (control of normal growth) tibia	3
No measure (control of normal growth) radius	4
	<hr/> 404

The procedure at operation was as follows

Evipan 14 supplemented with ether was used as anaesthetic. After the animal had been anaesthetized the extremity was shaved to the required extent. A longitudinal incision was made through skin and fascia 12–15 mm long. The musculature was bluntly parted. In the periosteum a door shaped flap about 5 × 5 mm was cut and folded upwards taking care that it did not reach the level of the growth plate during loosening. Centrally in the periosteal opening a hole was made with a dental drill at right angles to the longitudinal axis of the bone. In the case of the metaphyseal drillings it was relatively easy to distinguish the growth plate and to place the drill hole at the intended distance from it. Regarding tibia the drill hole was throughout placed tibially in radius dorsally. Left leg was operated on consistently.

Thus, after the experimental animals had arrived, been weighed and observed for about 3 days, a first OTC-injection (section zone A) was made 24 hours later, with a maximum margin of error of ± 5 minutes (according to *Hansson's* normal growth curves 1967, corresponding to a growth of approximately ± 2 microns), a new weighing and a new OTC injection (zone B), and immediately thereafter drilling were made 24 hours after B, weighing and injection (zone C) followed 24 hours after C weighing and injection (zone D) were repeated. The animal was then killed. The preparing was carried out according to the previously given principles. Sections, usually 3 from each growth region, were taken from the proximal and distal growth regions bilaterally, thus from both the operation side and the control side, in radius or tibia, according to where the operation was performed.

In the sections from each of these 4 growth regions 5 measurements (distributed, if possible, on the 3 sections) were then made of the distance A—B, 5 of B—C, and 5 of C—D. Thus from each experimental animal 60 measurements were obtained. However quite often, for various reasons it was not possible to get 5 measurements from each growth region for the 24-hour growth. If fewer than 3 measurements were obtained, this 24 hour value was discarded as was the corresponding measurement for the contralateral growth region for the same 24-hour period.

For uniformity of judgement the author carried out all measurements. The metaphyseal front of each OTC-band was chosen as measuring point (according to *Hansson* 1967).

After a number of 3 twenty-four hour period recordings of this type were obtained, it was decided to study the course of the growth over a longer time from the trauma. According to the same schedule as above and maintaining the 24 hour interval between the OTC injections a series of data were collected for different 3 twenty-four hour periods from the time of the operation up to the tenth postoperative 24 hour period as evenly distributed as possible.

The day after the operation the animals fed and moved normally, as far as could be judged. Infection of the operation wounds was noted on only three occasions and these animals were rejected from the series.

Besides these six different drillings a few sham operations were carried out: 6 on tibia and 6 on radius. This was to discover any possible growth disturbing effect from merely skin and muscle incisions. For similar purposes 15 animals given only narcosis were investigated. These last mentioned investigations followed the original time schedule (pre operative 24 hours \pm 2 postoperative 24 hours).

Fig 19 Front and side of tibiofibula in rabbit The position of the three drillings is indicated

The drilling was done in stages to avoid the generation of heat. As soon as the medullary cavity was reached, rotation was stopped and the now stationary drill was pushed in towards the opposite wall. When the cavity was penetrated, there was usually moderate bleeding at proximal and diaphyseal tibial drilling otherwise none. The bleeding, however, usually ceased when the wound was sutured (silk) and no postoperative haematoma worth mentioning was noted. The wounds were not bandaged.

Fig 20 Front and side of radius in rabbit The position of the three drillings is indicated

CHAPTER IX

RESULTS

A Remarks on sources of error

Although growth determination with oxytetracycline labelling can in the main be said to be a relatively simple method some difficulties arose at the investigation. As elaborated in more detail by *Hansson* (1967) the *fluorescing* zones become successively weaker during their seeming progress in diaphyseal direction which of course is due to the movement of the growth plate in epiphyseal direction. This applies to both tibia and radius to about the same extent. The last three injections as a rule resulted in quite *distinct* lines in the preparation. There was no difficulty in measuring between these zones. The first injection administered 72 hours before killing the animal on the other hand was frequently weak and diffuse therefore measurement of the interval between the OTC lines A and B (cf p 000) could not be carried out on every occasion.

The postoperative development of a tongue of cartilaginous cells from the growth plate down in the metaphysis (cf *Hansson* 1967) could sometimes considerably restrict the space for transversally running fluorescing bands thereby reducing the possibility of repeated measurements in one and the same section.

The growth potential of the proximal growth plate in radius is only about 20 % of that in the distal radius and in the two ends of tibia. The intervals (i.e. the daily growth) measured in the proximal radius metaphysis were 80–130 μ wide and the measuring scale was graded in 10 μ units. It is then easily understood that the percentage error in measurement must have been considerably greater in the proximal radius than in the other three growth regions studied here, with a daily growth of 400–500 μ (cf below).

Of error factors otherwise the toxic effect of OTC already mentioned does not appear to have played any role. An incorrect orientation of the cuttings could result in considerable distortion of the measuring intervals but such a faulty oblique cutting is fairly clearly reflected in the appearance of the trabeculae in the preparation.

E Additional statistical methods

The statistical analysis of the experimental study results have in the main followed the same line as given on pp 000. As statistical working model, the following differences were used

$$d_{ij} = X_{Fij} - X_{Cij} \quad \text{where} \quad \begin{array}{ll} i = 1, 2, 3 & n \text{ (animals)} \\ j = 1, 2, 3 & (24 \text{ hour-periods}) \end{array}$$

X_{Fij} is the measurement value for the fractured bone of the i^{th} animal after the j^{th} day

X_{Cij} is the measurement value for the control bone of the i^{th} animal after the j^{th} day

The same model was arranged for the three different drilling places in combination with two bone types (radius, tibia) and two measurement places

This model was chosen in order that any possible weight effect could be eliminated by using the differences because the weight effect must be considered to be equally great for fractured bone and control bone

The analysis was made with the aid of one sided variance analysis (t-analysis) whereby the interest was primarily concentrated on possible differences between the 24 hour periods (Snedecor 1962, Guenther 1964)

B Effect of drilling on growth rate

1 Operated bone

Tibia (proximal drilling) Fig 21 22 Table 6

Proximal growth plate the growth rate shows an almost significant acceleration for the first second and third postoperative 24 hour periods whereafter there is a fall to statistically not guaranteed differences up to and including the sixth 24 hour period. The seventh and eighth 24 hour periods again show an almost significant acceleration whereafter the growth during the ninth and tenth 24 hour periods approaches more and more that of the control bone.

Fig 21

Proximal drilling of tibia

Age days increase in growth from the proximal growth plate

Distal growth plate the reaction of the distal epiphysis is highly significant and reaches a maximum during the third to fifth postoperative 24 hour periods although almost significant acceleration can be observed as early as the first 24 hour period after the drilling. Also concerning the distal epiphysis there is a tendency to a second maximum at the seventh 24 hour period, but the number of observations here are relatively few and the significance uncertain. It is conspicuous that the reaction from the distal

The existence of a litter effect, a product of hereditary and environmental factors and shown by *Hansson* (1967) to have a significant influence on the rate of growth, was counteracted by animals from one and the same litter always being split up on various types of drillings and one type of drilling always being performed on animals from at least three different litters

The total systematic error of method at a single measurement has been calculated statistically (col A below). However, the values used for growth calculations were arithmetic means based on 5 measurements and the error of method for these values (col B) was consequently reduced by a

$$\text{factor} = \frac{1}{\sqrt{5}}$$

	A	B	B expressed in % of average daily growth
Tibia proximal growth plate	17.3 μ	7.7 μ	1.4
Tibia distal growth plate	14.4 μ	6.4 μ	1.5
Radius proximal growth plate	8.1 μ	3.6 μ	2.8
Radius distal growth plate	10.5 μ	4.7 μ	1.1

The growth thus recorded is the diaphyseal growth. As pointed out on p. 000 this does not correspond exactly to the growth recorded in *Part One*, where also the growth of the bony epiphysis is included. According to *Hansson* (1964), however, the epiphyseal proportion of the total growth of the bone in rabbit at this age period is less than 1/5 of the diaphyseal and it was deemed possible to disregard this fraction in the following discussions of the experimental and clinical results.

B Effect of drilling on growth rate

1 Operated bone

Tibia (proximal drilling) Fig 21 22 Table 6

Proximal growth plate the growth rate shows an almost significant acceleration for the first second and third postoperative 24 hour periods whereafter there is a fall to statistically not guaranteed differences up to and including the sixth 24 hour period. The seventh and eighth 24 hour periods again show an almost significant acceleration whereafter the growth during the ninth and tenth 24 hour periods approaches more and more that of the control bone.

The growth thus recorded is the diaphyseal growth. As pointed out on p. 000 this does not correspond exactly to the growth recorded in Part One, where also the growth of the bony epiphysis is included. According to *Hansson* (1964), however, the epiphyseal proportion of the total growth of the bone in rabbit at this age period is less than 1/5 of the diaphyseal and it was deemed possible to disregard this fraction in the following discussions of the experimental and clinical results.

seventh partly highly significant values with a probable maximum during the third to sixth 60 μ . No tendency to a second maximum appears

Fig 24

Mid diaphyseal drilling of tibia

Average daily increase in growth from the distal growth plate

Distal growth plate Here a strong reaction is recorded with highly significant values during the first and second postoperative days where after the overgrowth becomes even more intense and reaches a maximum during the third to the fifth 24 hour periods where the absolute values are 60 to 65 μ . From and including the sixth period a regress occurs and from and including the eighth no statistically guaranteed difference compared with the control bone can be recorded

In this series a strange incongruity appears the growth already shows a significant increase pre operatively compared with the control bone. Careful examination of the preparations and the records of the experimental animals gave no explanation for this phenomenon which however is not absurd from a statistical standpoint. Probably its occurrence suggests that the recorded growth acceleration during the postoperative first and second 24 hour periods must be granted limited statistical significance

Fig 22

Proximal drilling of tibia

Fig 25

Distal drilling of tibia

Average daily increase in growth from the proximal growth plate

Tibia (distal drilling) Fig 25, 26 Table 8

Proximal growth plate The first postoperative 24-hour period shows an almost significant growth increase, which has full significance the following 5 days and where a maximum is judged to be present during the third to fifth 24 hour periods. The absolute value of this maximum probably does not exceed 60 μ , because the extremely high peak (74 μ) in the third period

Fig 26

Distal drilling of tibia

Average daily increase in growth from the distal growth plate

is based on rather few measuring values. From and including the seventh 24 hour period the growth has slowed down to that of the control bone without reliable signs of any second maximum.

Distal growth plate Inconclusive reaction with some tendencies to both growth acceleration and retardation. A significant overgrowth value for the seventh 24 hour period is based on comparatively few observations. Besides there is a tendency although less pronounced to the same discrepancy between the preoperative growth of the two bones as noted in the series of mid diaphyseal drillings.

Radius (proximal drilling) Fig 27 28 Table 9

Proximal growth plate The difference in growth rate during the pre-operative 24 hours compared with the control bone has no statistical significance. In agreement with the slight growth potential of the proximal growth plate the reactions on the whole are small and statistically guaranteed acceleration is observed only during the first postoperative 24 hour period whereas the fluctuations of the curve otherwise lack significance.

Fig 29

Distal drilling of radius

Average daily increase in growth from the proximal growth plate

Radius (distal drilling) Fig 29 30 Table 11

Proximal growth plate as expected with regard to the slight growth potential of this region the response to the drilling was slight. Almost significant reaction however is shown during the second postoperative 24 hour period otherwise the results have no statistical significance. As at proximal drilling in tibia a slight tendency to two maxima can be discerned one at the second postoperative 24 hour period and one at the ninth to tenth but this observation is uncertain.

Distal growth plate almost significant to highly significant reaction is obtained during the first to second postoperative 24 hour periods whereafter successive equalization takes place.

Fig 30

Distal drilling of radius

Average daily increase in growth from the distal growth plate

Fig 28

Proximal drilling of radius

Average daily increase in growth from the distal growth plate

Distal growth plate concerning the pre-operative 24 hour period the same condition applies as for the proximal growth plate. A significant acceleration is found during the first postoperative 24-hour period, and a high significance during a maximum in the third to fifth periods whereafter a slow regress occurs. The maximum value in the fourth 24 hour period appearing on the curve is based on only 4 observations and must be considered fairly uncertain. The actual absolute maximum value probably lies lower around 45μ .

Radius (mid diaphyseal drilling) Table 10

Proximal growth plate the course of the curve above the x axis indicates only a slight and uncertain tendency to overgrowth without statistical significance for any 24-hour period. Because of the absence of distinct positive or negative growth reaction diagrammatic representation has been omitted.

Distal growth plate although the curve reaches relatively high peaks in the second and the fourth 24 hour periods the spreading in the observations is none the less large and the reaction has no statistical significance for any 24 hour period. This investigation was considerably disturbed by a strong development of tongues of cartilaginous cells (cf p 000) the number of observations were therefore particularly few in this series. Diagram omitted.

Fig 29

Distal drilling of radius

Average daily increase in growth from the proximal growth plate

Radius (distal drilling) Fig 29 30 Table 11

Proximal growth plate as expected with regard to the slight growth potential of this region the response to the drilling was slight. Almost significant reaction however is shown during the second postoperative 24 hour period otherwise the results have no statistical significance. As at proximal drilling in tibia a slight tendency to two maxima can be discerned one at the second postoperative 24 hour period and one at the ninth to tenth but this observation is uncertain.

Distal growth plate almost significant to highly significant reaction is obtained during the first to second postoperative 24 hour periods where after successive equalization takes place.

Fig 30

Distal drilling of radius

Average daily increase in growth from the distal growth plate

2 Control bone

In this investigation, the growth of the control bone during the first and second postoperative 24 hour periods was compared with the growth during the pre-operative 24-hour period, with t analysis. In agreement with Hansson's (1967) investigation, growth retardation can here be recorded in most instances. The results were as follows (cf Table 12)

Proximal drilling of tibia

Proximal growth plate highly significant retardation during the first and second postoperative 24 hour periods. Average retardation for 2 periods, 35 "

Distal growth plate highly significant retardation during the first postoperative period, almost significant the second. Average retardation for 2 periods, 24 "

Mid diaphyseal drilling of tibia

Proximal growth plate almost significant retardation during the first postoperative period, no significance during the second. Average retardation for 2 periods, 16 "

Distal growth plate no significant change in growth during any of the investigated periods. Average retardation is 22 " but the spreading is large.

Distal drilling of tibia

Proximal growth plate highly significant growth retardation during the first and second postoperative periods. Average retardation for 2 periods, 30 "

Distal growth plate highly significant retardation during the first postoperative period, significant during the second. Average retardation for 2 periods, 26 "

Proximal drilling of radius

Proximal growth plate no significant retardation during the first two postoperative periods

Distal growth plate almost significant growth retardation during the first postoperative period. Slight acceleration of 14 " during the second but without significance (the only acceleration noted in the control bone during the period in question at any of the drillings)

Mid diaphyseal drilling of radius

Because of few usable complete 3 twentyfour hour series no statistical analysis was made on this material

Distal drilling of radius

Proximal growth plate almost significant retardation and this only during the first postoperative period

Distal growth plate significant retardation during the first postoperative period Non significant reaction during the second

C Control experiments

1 Sham operations

With the object of discovering whether skin incision and muscle incision up to, but not through, the periosteum can affect growth 12 rabbits were operated on in this manner 6 on the proximal radius, and 6 on the proximal tibia. The investigation included the first three postoperative 24 hour periods. Tetracycline labelling was done according to the same norms as for the other material. For none of the studied periods, do any of the bones show statistically demonstrable difference concerning growth either for the proximal or for the distal growth regions. The results are reported in table nr 13 (see Appendix)

Fig 31 Growth percentage from proximal and distal growth plates in tibia and radius of the rabbit estimated from 15 non-operated animals

2 Control rabbits (narcosis)

An investigation was made concerning growth in 15 rabbits taken from different litters and given narcosis during the 24 hour period before and the two periods after the narcosis. In agreement with earlier investigators (Hansson 1967) no statistically demonstrable differences whatever were obtained between the three periods in other words the narcosis had no effect. These 15 animals were therefore regarded as normal material and on the basis of their growth the percentage size of the systematic error ($P = 82$) was calculated. By combining the values of the three periods the percentage growth from the proximal growth regions in tibia and in radius was also calculated whereby the following confidence intervals were obtained

Tibia

$$P = (55.2 \pm 1.5) \%$$

Radius

$$P = (19.6 \pm 1.3) \%$$

According to this investigation the proximal growth rate in rabbits of this age in tibia is thus 55 % and the distal 45 % whereas the corresponding values for radius is 20 % and 80 % respectively.

C Control experiments

1 Sham operations

With the object of discovering whether skin incision, and muscle incision up to, but not through, the periosteum can affect growth, 12 rabbits were operated on in this manner 6 on the proximal radius and 6 on the proximal tibia. The investigation included the first three postoperative 24 hour periods. Tetracycline labelling was done according to the same norms as for the other material. For none of the studied periods, do any of the bones show statistically demonstrable difference concerning growth, either for the proximal or for the distal growth regions. The results are reported in table nr 13 (see Appendix)

Fig 31 Growth percentage from proximal and distal growth plates in tibia and radius of the rabbit estimated from 15 non operated animals

CHAPTER X

DISCUSSION

The experimental operations on tibia — reported in previous chapters — seem to have so pronounced and unambiguous effect that an error factor would have to be very considerable to produce faulty results. The same applies to proximal drilling of radius whereas drilling centrally or in the distal metaphysis of the same bone gave uncertain values. The statistical analysis method has eliminated possible weight factor. The sex of the animals at the age of 30—40 days has no influence on the growth rate (Hansson 1967). The systematic errors for a single measurement in proximal and in distal tibia is indicated on p. 82 as 17.3 and 14.4 μ respectively (i.e. about the same size as that given by Hansson 1967) and does not affect the statistical evidence. The results from distal radius can be appraised according to the same norms. The values from the proximal growth region of radius are lower which might be largely due to the slight growth rate from its growth plate. Here the absolute value of the systematic error is actually lower 8.1 μ ; this, however with regard to the low growth rate is in per cent an error of method fully twice as large as in other investigated growth regions.

As earlier mentioned (p. 63) the object of the experimental investigation was to find out whether a varying localization of fractures in a growing long bone gave different growth stimuli. It was therefore natural to study in more detail the reaction from the proximal and the distal growth regions in a long bone after an experimental trauma. For this reason the discussion here is restricted to the relation between trauma localization and increased growth from the two growth plates of a long bone.

At a study of Fig. 21 and 22 (proximal tibia drilling) and Fig. 25 and 26 (distal tibia drilling) it is obvious that the growth plate lying farthest from the trauma shows the strongest reaction which is most evident after distal drilling. This is verified by the statistical calculation.

A comparison with the post-traumatic reaction from the growth plates of radius reveals that the relation is similar in this bone concerning proximal drilling whereas distal trauma gave no significant differences. This is

D Summary of the results

Operated bone	Position of the drill trauma	Growth reaction	
		Proximally	Distally
Tibia	proximal	+	+++
	mid diaphyseal	+++	+++
	distal	+++	+(+)
Radius	proximal	+(+)	+++
	mid-diaphyseal	0	0
	distal	+	+++

The grading in the above table follows the statistical evaluation. Thus 0 does not indicate total absence of all reaction but only that statistical significance for such is lacking.

both instances important for the growth process in adjoining growth region *Hansson* (1967) as mentioned earlier, demonstrated that where the trauma is extra medullary and restricted to a limited area of the cortical bone tissue or periosteum a growth stimulus is obtained both in the proximal and in the distal growth region of the same long bone it is therefore of importance whether or not the circulation paths of the growth region are intact

This investigation similar to earlier growth studies (*Brodin* 1955, *Elo* 1960 *Hansson* 1967) thus strongly argues against the opinion held by *Trueta* (1953 1956) *Taillard & Morscher* (1965) *Yabsley & Harris* (1965) These have asserted that a medullary trauma like extensive periosteal stripping stimulates the growth from the adjoining growth region by increasing the blood flow through the remaining blood vessels Results submitted here indicate on the other hand that a fracture equivalent trauma to long bones results in considerable vascular destruction in adjoining growth region which cannot be overcompensated by hyperaemia so that the growth here is unable to increase (and possibly be temporarily retarded, cf *Hansson* 1967) whereas an obvious growth stimulus appears early within the more distant growth plate

There is much that argues for growth stimulus being related to hyperaemia in the growth region involved This is also supported by investigations of *Wray et al* (1960 1961) and *Sunden* (1967) who found a positive correlation between blood flow and growth rate as well as *Persson* (1968) who found a positive correlation between oxygen tension and growth rate In accordance with this after a metaphyseal trauma such as those under discussion hyperaemia should be expected mainly within the remoter growth region and not or at least to a much lesser degree around the nearest growth plate This presumption might be checked further by several experimental methods

The diaphyseal drillings in tibia produced clearly significant and approximately equally strong reactions from both growth plates The increase in length of the long bone resulting from the experiments was therefore probably most considerable at mid diaphyseal drilling of tibia This result might be explained by the loss of the blood supply through the nutrient vessels caused by the drill trauma being probably thoroughly compensated by remaining vessels to the growth regions

With regard to the fact that *Hansson* (1967) noted changed growth rate (retardation) in the control bone after trauma to tibia the present author's statistical analysis also included an investigation of whether the control bone is affected by drilling in the contralateral bone In good agreement with *Hansson's* observations obvious retardation was obtained from the

easily understandable because the growth rate in the proximal growth region of radius is low compared with other studied regions. It must be pointed out at the same time that the systematic error for this growth plate is greater than for the other three because of its small size and the thereby created sectioning difficulties. On the basis of these observations in radius and tibia, it seems reasonable to conclude that metaphyseal drilling or fracture in growing long bone is followed by strong growth stimulus from the growth plate at the opposite end of the bone and slight (or no) acceleration from that lying nearest. Earlier experimental investigations support this concept. Thus *Brodin* (1955) could demonstrate that periosteal stripping in the proximal part of the tibia diaphysis in rabbit is regularly followed by a growth increase from the distal growth plate, and after a shorter initial acceleration by a slowing down of the growth from the proximal growth plate. *Brodin* assumed that the lesion of proximal perforating metaphyseal vessels caused, to some extent at least, the proximal growth retardation.

Reidy, Lingley, Gall & Barr (1947) studied the effect of roentgen radiation on skeletal growth and could regularly demonstrate retarded growth from irradiated proximal epiphyseal region of the tibia and accelerated growth from the untreated distal growth zone of the same bone. The authors suggested hyperaemia as a possible cause of this distal reaction.

A distinct and fully significant reaction from the distal growth plate was obtained by *Hansson* (1967) after plugging of the medullary cavity in the proximal part of the tibia in rabbit. The proximal growth plate showed initially a slight growth acceleration which was followed by a prolonged retardation of the growth rate.

The results from the author's investigation thus agree well with those from the above mentioned studies. The present investigation, moreover, clearly revealed that a trauma of the distal metaphysis in tibia produces pronounced growth stimulus in the proximal growth region of the same long bone whereas the effect distally has much less significance. A corresponding reaction pattern was also demonstrated in radius, whose largest growth occurs from its distal growth region as distinct from the condition in tibia. Thus the reaction pattern is the same irrespective of whether it refers to the upper or lower extremity or whether the most rapidly growing growth region is situated proximally or distally.

It must be pointed out however that this probably applies only if the trauma affected and destroyed the medullary vessels (fracture, osteotomy, medullary cavity drilling or plugging) and/or sufficient number of the perforating metaphyseal blood vessels (periosteal stripping) which are in

both instances important for the growth process in adjoining growth region *Hansson* (1967) as mentioned earlier demonstrated that where the trauma is extra medullary and restricted to a limited area of the cortical bone tissue or periosteum a growth stimulus is obtained both in the proximal and in the distal growth region of the same long bone it is therefore of importance whether or not the circulation paths of the growth region are intact

This investigation similar to earlier growth studies (*Brodin* 1955 *Elo* 1960 *Hansson* 1967) thus strongly argues against the opinion held by *Trueta* (1953 1958) *Taillard & Morscher* (1965) *Yabsley & Harris* (1965) These have asserted that a medullary trauma like extensive periosteal stripping stimulates the growth from the adjoining growth region by increasing the blood flow through the remaining blood vessels Results submitted here indicate on the other hand that a fracture equivalent trauma to long bones results in considerable vascular destruction in adjoining growth region which cannot be overcompensated by hyperaemia so that the growth here is unable to increase (and possibly be temporarily retarded cf *Hansson* 1967) whereas an obvious growth stimulus appears early within the more distant growth plate

There is much that argues for growth stimulus being related to hyperaemia in the growth region involved This is also supported by investigations of *Wray et al* (1960 1961) and *Sunden* (1967) who found a positive correlation between blood flow and growth rate as well as *Persson* (1968) who found a positive correlation between oxygen tension and growth rate In accordance with this after a metaphyseal trauma such as those under discussion hyperaemia should be expected mainly within the remoter growth region and not or at least to a much lesser degree around the nearest growth plate This presumption might be checked further by several experimental methods

The diaphyseal drillings in tibia produced clearly significant and approximately equally strong reactions from both growth plates The increase in length of the long bone resulting from the experiments was therefore probably most considerable at mid diaphyseal drilling of tibia This result might be explained by the loss of the blood supply through the nutrient vessels caused by the drill trauma being probably thoroughly compensated by remaining vessels to the growth regions

With regard to the fact that *Hansson* (1967) noted changed growth rate (retardation) in the control bone after trauma to tibia the present author's statistical analysis also included an investigation of whether the control bone is affected by drilling in the contralateral bone In good agreement with *Hansson's* observations obvious retardation was obtained from the

easily understandable because the growth rate in the proximal growth region of radius is low compared with other studied regions. It must be pointed out at the same time that the systematic error for this growth plate is greater than for the other three because of its small size and the thereby created sectioning difficulties. On the basis of these observations in radius and tibia, it seems reasonable to conclude that metaphyseal drilling or fracture in growing long bone is followed by strong growth stimulus from the growth plate at the opposite end of the bone and slight (or no) acceleration from that lying nearest. Earlier experimental investigations support this concept. Thus *Brodin* (1955) could demonstrate that periosteal stripping in the proximal part of the tibia diaphysis in rabbit is regularly followed by a growth increase from the distal growth plate, and after a shorter initial acceleration, by a slowing down of the growth from the proximal growth plate. *Brodin* assumed that the lesion of proximal perforating metaphyseal vessels caused to some extent at least, the proximal growth retardation.

Reidy, Lingley, Gall & Barr (1947) studied the effect of roentgen radiation on skeletal growth and could regularly demonstrate retarded growth from irradiated proximal epiphyseal region of the tibia and accelerated growth from the untreated distal growth zone of the same bone. The authors suggested hyperemia as a possible cause of this distal reaction.

A distinct and fully significant reaction from the distal growth plate was obtained by *Hansson* (1967) after plugging of the medullary cavity in the proximal part of the tibia in rabbit. The proximal growth plate showed initially a slight growth acceleration which was followed by a prolonged retardation of the growth rate.

The results from the author's investigation thus agree well with those from the above mentioned studies. The present investigation more over clearly revealed that a trauma of the distal metaphysis in tibia produces pronounced growth stimulus in the proximal growth region of the same long bone, whereas the effect distally has much less significance. A corresponding reaction pattern was also demonstrated in radius whose largest growth occurs from its distal growth region as distinct from the condition in tibia. Thus the reaction pattern is the same irrespective of whether it refers to the upper or lower extremity or whether the most rapidly growing growth region is situated proximally or distally.

It must be pointed out, however that this probably applies only if the trauma affected and destroyed the medullary vessels (fracture osteotomy, medullary cavity drilling or plugging) and/or sufficient number of the perforating metaphyseal blood vessels (periosteal stripping) which are in

Summing up the principal results it can thus be said

that proximal drill trauma through the medullary cavity in growing rabbit tibia results in powerful increase in growth distally

that distal drill trauma in the same long bone gives a powerful increase in growth proximally and

that several criteria argue for such a growth reaction being a general phenomenon

two growth plates of the control bone after most types of drillings. This reaction appears to be most powerful in the growth regions that have the highest growth potential in each bone: the proximal growth plate in tibia and the distal growth plate in radius.

It seems remarkable that mid diaphyseal tibia drilling, which triggers off the most powerful total growth acceleration in the operated bone, also produces a very weak retardation in the control bone. This may however be ascribed to the anatomical conditions in the mid diaphyseal region being such that an exposure of the shaft is easy and less traumatic to the soft parts than a dissection of the metaphyses. In other words, the general debilitating effect of the experimental operations is probably slightest at drillings of the tibia diaphysis.

Repeated allusions (p. 87, 96) have been made to a supposition that overgrowth probably is more pronounced in growth regions with a high growth potential. This may be a reasonable assumption but has no factual foundation. Some viewpoints on this question can be extracted from the present material.

In rabbit tibia the proportions of growth from proximal and distal growth plates are found to be 55 % and 45 % respectively (p. 93). For such a slight difference to be mirrored with certainty in the recordings of overgrowth a very large material is required. At a comparison between the diagrams for proximal growth plate reaction on distal drilling (Fig. 25) and distal growth plate reaction on proximal drilling (Fig. 22) a certain difference can no doubt be perceived: where the proximal growth plate shows the strongest reaction (maximum 60 μ in contrast to 45 μ for the distal growth plate). However, statistical significance cannot be ascribed to this difference.

If we look at the corresponding values within radius (Fig. 29-28) where proximal and distal growth contributions are 20 % and 80 % respectively, a clear difference is observed with a maximum for the proximal plate at 10 μ and for the distal at about 40 μ . That the proportions for radius happen to fit exactly should be regarded as a chance coincidence but even with appropriate criticism some evidence must be considered to exist for the supposition that the amount of overgrowth is correlated to the natural growth potential of the region in question.

It should also be mentioned here that the experimental results refer to the initial reaction whereas the clinical results refer to the growth reaction 3 months or more after the fracture when the healing had reached an advanced stage. Moreover at the clinical investigation the change was recorded in the total length of the long bone — diaphysis cartilage plates and bony epiphyses — whereas solely the growth of the diaphysis was measured in the different growth plates of the long bone at the experimental investigation.

The experimental trauma that resulted in the strongest total increase in length was drilling in the centre of the tibia diaphysis whereby both proximal and distal growth plates reacted with high significance and large absolute measuring values. If analogous conditions exist concerning humerus in *homo* it could be expected that the diaphysary humerus fractures would give the strongest increase in growth as suggested by Calati & Poli 1959. This is not so in the present material where the dislocated diaphysis fractures show accumulated overgrowth of 7 mm compared with 9 mm for *collum chirurgicum* fractures and 9 mm for dislocated supracondylar fractures.

Also here there is the reservation of course that the experimental and the clinical investigations from physiological aspect do not take place in the same period. The *foramen nutritium* in humerus in *homo* moreover is situated somewhat below the most often observed level for diaphyseal fractures whereas *foramen nutritium* in rabbit tibia lies on about the same level as the point where the diaphysary drill holes are made. It is therefore conceivable that a diaphysis fracture in humerus in *homo* is sometimes more likely to correspond to the proximal drill trauma in rabbit tibia than to the trauma to the centre of the tibia diaphysis. In cases of this nature it can be expected that humerus fractures in diaphysis and within *collum chirurgicum* must trigger off growth acceleration of about the same size. This occurred in the present material but the number of observations is not large enough to confirm with any certainty the above reasoning.

CONCLUDING REMARKS ON THE CLINICAL APPLICATION OF THE EXPERIMENTAL RESULTS

As pointed out in the introduction the growth rate in humerus in *homo* differs considerably in the proximal and distal growth plates the relation being given as 3:1 by a couple of investigators (Bergmann 1928—29, Emneus & Hedstrom 1964). If the experimental results are universal for the effects of fractures on the growth regions of long bones, it could be expected that a supracondylar humerus fracture would stimulate the proximal growth plate and that a fracture through *collum chirurgicum* would, in the main, influence the distal growth zone. With reference to the mentioned relation between the growth rates, a supracondylar fracture should produce considerably greater growth stimulus than a *collum chirurgicum* fracture comparable regarding dislocation and age of the individual.

As seen in Chapter IV, the accumulated average growth concerning fractures through *collum chirurgicum* was in the present material 9 mm and concerning dislocated supracondylar fractures also 9 mm after 40 months. This evidently contradicts the hypothesis on trial. However, a comparison such as the actual one is fraught with fallacies. As previously stated (p. 35) there was found a significant age difference in this material between supracondylar fractures on the one hand, fractures through diaphysis and surgical neck on the other. This may in itself be of minor importance since substantial differences concerning the size of overgrowth at different age periods could not be demonstrated. Another question is whether the physiological (not clinical) healing time is on the same scale in supracondylar fractures and fractures through the surgical neck. If this is not so and here data are lacking one may expect — *ceteris paribus* — that the fracture type with the slower healing will show a stronger overgrowth than is indicated by its ordinary growth potential.

Other reservations could be raised such as differences in vascular anatomy between various long bones and the difficulty of comparing displacement in fractures. Taken together these objections imply that the present clinical material hardly allows for a comparison aiming at a verification of the experimental results. They also mean that the hypothesis propounded is neither proved nor disproved but stands open to further inquiry.

It should also be mentioned here that the experimental results refer to the initial reaction whereas the clinical results refer to the growth reaction 3 months or more after the fracture when the healing had reached an advanced stage. Moreover at the clinical investigation the change was recorded in the total length of the long bone — diaphysis cartilage plates, and bony epiphyses — whereas solely the growth of the diaphysis was measured in the different growth plates of the long bone at the experimental investigation.

The experimental trauma that resulted in the strongest total increase in length was drilling in the centre of the tibia diaphysis whereby both proximal and distal growth plates reacted with high significance and large absolute measuring values. If analogous conditions exist concerning humerus in *homo* it could be expected that the diaphysary humerus fractures would give the strongest increase in growth as suggested by Calati & Poli 1959. This is not so in the present material where the dislocated diaphysis fractures show accumulated overgrowth of 7 mm compared with 9 mm for *collum chirurgicum* fractures and 9 mm for dislocated supracondylar fractures.

Also here there is the reservation of course that the experimental and the clinical investigations from physiological aspect do not take place in the same period. The *foramen nutritium* in humerus in *homo* moreover is situated somewhat below the most often observed level for diaphyseal fractures whereas *foramen nutritium* in rabbit tibia lies on about the same level as the point where the diaphysary drill holes are made. It is therefore conceivable that a diaphysis fracture in humerus in *homo* is some times more likely to correspond to the proximal drill trauma in rabbit tibia than to the trauma to the centre of the tibia diaphysis. In cases of this nature it can be expected that humerus fractures in diaphysis and within *collum chirurgicum* must trigger off growth acceleration of about the same size. This occurred in the present material but the number of observations is not large enough to confirm with any certainty the above reasoning.

SUMMARY

At the Orthopaedic Clinic in Lund in 1955 systematic follow up investigations were begun of children who had suffered any of the following forms of humerus fractures

supracondylar fracture

diaphysis fracture

collum chirurgicum fracture

The aim was to investigate with the aid of roentgenological measurement to what extent growth stimulus after fracture in growing bone, well known in femur and tibia, also has its equivalent in humerus moreover and primarily, to map in closer detail the development of such a stimulus. The intention was to find when it began and when it ended, and also to study whether the extent of the increase in growth could be set in relation to such parameters as the age of the patient, the dislocation of the fracture, and its distance from the two growth plates in humerus.

The studies were carried out with orthodiagraphic measurement technique, and such measurements were intended to be made in long series with regular time intervals for as long a period as increase in growth could be demonstrated or expected. Preliminary investigations during the first years showed that such growth acceleration occurred in high frequency for the first two years after the fracture, and that it could result in demonstrable differences up to 15 mm in humerus length.

It proved difficult to get enough patients and to carry out a sufficient number of investigations on them. Finally 86 patients who could be used for statistical analysis were obtained. Of these 60 had suffered supracondylar fractures, 8 diaphysary and 18 *collum chirurgicum*. The representation of the two latter categories was definitely insufficient for statistical analysis of the extent planned.

The studies were carried out with simultaneous measurement of right and left humerus. Because the length of the bone on the roentgen picture equalled the actual length it was possible to obtain the measurements of the two humeri and their mutual difference directly without recalculation. Series of such differences in length were obtained at different times after

the fracture where in most favourable cases an initial measurement was made one month after the fracture and then with usually 3 month intervals up to 10 length recordings

After the clinical investigation was ended a somewhat inhomogeneous material was at hand of varying measuring frequency and somewhat irregular measuring intervals. The analysis of this however showed that the size of the overgrowth probably also its duration is positively correlated to the degree of dislocation. A maximum for the growth acceleration could also be demonstrated 12—18 months after the fracture whereas the onset of the increase in growth could not be determined with certainty. Its termination could not be established definitely but overgrowth could with some probability be shown to continue for at least 20 months.

An attempt was made to appraise the possible relation of growth acceleration to age. The statistical basis however was scanty and guaranteed differences between children less than 4 years of age and those more than 4 years of age could not be demonstrated.

- In conclusion the clinical investigation had proved
- that overgrowth after humerus fracture is a very common possibly obligatory phenomenon (frequency in this material 80 %)*
 - that the dislocation with certainty is positively correlated to the size of overgrowth probably also to its duration*
 - that the curve for the growth acceleration shows a maximum at 12—18 months whereas particularly its starting point could not be established and its end point in any event lay beyond 20 months possibly — for considerably dislocated fractures — at about 3 years*
 - that no obvious difference in growth acceleration between different age groups could be established*

At the beginning of the work it was expected that a close analysis of the three different types of extraepiphyseal fractures in humerus would solve the question of the importance of the fracture level for the growth stimulation. These hopes were vain partly because of the insufficient material for this purpose and partly because an original plan to insert a metal indicator in the humerus diaphysis where it should function as a fixed point for the measurements had to be abandoned on both technical and ethical grounds. For these reasons an experimental study was motivated in order to provide information about the possible relation between fracture level and

overgrowth which could not be extracted from the clinical study. A plan was devised to determine the growth rate of long bone experimentally, with the aid of oxytetracycline markings and by bone drillings equivalent to fractures, in an attempt to solve the problem.

For this purpose, 404 rabbits, aged 4—5 weeks were used. Tibia and radius were chosen to be operated on. For each kind of bone, three different experimental series were made with drillings in the proximal metaphysis, the diaphysis, and the distal metaphysis. The growth/24-hours was determined during 3 24-hour periods for the operated long bone as well as for its contralateral equivalent. The investigation period included the preoperative 24-hours and the 10 following 24-hour periods.

The statistical analysis of the measurement values revealed that drilling of proximal metaphysis in tibia and also in radius produced a slight increase in growth proximally and a very considerable increase distally. Inversely, distal tibia drilling resulted in a strong growth acceleration proximally and almost no reaction distally. Distal radius drilling did not trigger off any significant growth changes from any of the growth plates.

Because two different long bones show this type of post-traumatic growth reaction, and similar phenomena having been reported by other researchers, this could be thought to represent a general rule not only in long bones of the rabbit but possibly also in other mammals. If an attempt is made to trace its existence in the clinical material in this study, we expect *a priori* to find a considerably larger increase in growth after supracondylar humerus fracture than after *collum chirurgicum* fracture. Such a tendency is not to be found in the present material which, however, because of its limited extent does not allow either a positive or a negative statement in this respect.

The drillings made in the centre of the tibia diaphysis triggered off strong growth acceleration from both proximal and distal growth plates whereas corresponding drillings of radius gave similar results with considerably lower amplitude and doubtful significance.

Contrary to this, the diaphysary humerus fractures in *homo* show a comparatively insignificant increase in growth. This discrepancy compared with the experimental results can possibly be explained by the fractures in question often lying considerably proximally to *foramen nutritium humeri*, whereas tibia drilling was made in the immediate vicinity of *foramen nutritium tibiae*. In other words, that the medullary vascular lesion at the two different types of trauma lay on different levels.

In short the experimental investigation gave the following results

A drilling through cortex and medullary cavity placed at the proximal metaphysis gives a strong growth acceleration in both radius and tibia from the distal growth plate and a much slighter reaction from the proximal plate

Conversely a drilling at the distal metaphysis gives a strong reaction from the proximal growth plate of tibia and a slighter growth acceleration from the distal plate From radius a result with rather low significance however contradictory was registered

It is proposed that this mode of reaction be regarded as universal within mammalian long bones

The amount of overgrowth from a certain growth region is in all probability correlated to its natural growth potential

ACKNOWLEDGEMENTS

Various aspects of skeletal growth have been among the foremost research problems at the Orthopaedic Clinic in Lund for about 15 years. These studies, to date, have resulted in six monographs (including the present work) and many articles. The investigations carried out as team work were initiated and led by Professor G. Wiberg, head of the Clinic, who undertook the task not merely by virtue of his office, but also and primarily as an active and experienced scientist. I sincerely thank him for the guidance, encouragement, criticism, and advice he has always willingly given, even during extremely busy periods.

To the other members of this research team I express my gratitude for many fruitful discussions and much constructive criticism. First and foremost, my thanks go to Docent H. Enneus who did the basic work on the clinical humerus studies and who in his positive spirit introduced me into the field.

Docent L. I. Hansson has untiringly assisted me by word and deed, particularly in carrying out the experimental investigations. His profound knowledge of growth problems has been an especially valuable source of reference.

Laborator O. Norman has carefully considered and criticised the roentgenological measurements. Docent S. A. Ahlgren, B. Persson and G. Sundén have contributed valuable suggestions and observations during the progress of the work.

Fil. kand. L. E. Ek who carried out the statistical analyses readily accepted the often varying directives and tasks imposed on him.

For technical assistance, clerical assistance and similar duties I wish to thank Miss M. Rabenius, Mrs. L. Olofsson and Miss A. Svensborn. Artist N. Wagner has with his usual care and efficiency made the drawings.

The work was supported by grants from the Medical Faculty in Lund, from the AB Eirs Foundation and from the Swedish Medical Research Council (Proj. No. B 67 — 17 x — 2031 — 01, B 68 — 17 x — 2031 — 02, and B 69 — 17 x — 2031 — 03).

ACKNOWLEDGEMENTS

The theme of this study was suggested to me by Professor A. Langenskiöld M.D. Head of the Clinic for Orthopaedics and Traumatology of the University Central Hospital Helsinki. I am most grateful to Professor Langenskiöld for suggesting and supervising this thesis.

I would like to thank Professor L. Saxén Mag. Phil. M.D. for his very valuable advice and help.

I am very grateful to Dr. Clyde L. Nash Jr. M.D. Cleveland Ohio for his critical reading of the manuscript.

My thanks are due to Professor M. Sulamaa M.D. Docent B. Sundell M.D. and Dr. R. Kivilaakso M.D. for their critical advice. Furthermore I am indebted to Miss L. Mikkola who assisted in my animal experiments. I also wish to thank Mr. Kingsley Hart M.A. who revised the English manuscript.

Last but not least I wish to thank my wife Irja who has been untiring in encouraging me to complete this study.

The present investigation was aided in part by institutional grants from the Sigrid Juselius Foundation Helsinki.

Helsinki 1969

I INTRODUCTION

PURPOSE OF THE INVESTIGATION

Despite the increase in our knowledge of various malformations the etiology of many common deformities such as club foot and vertical talus remains unknown. Detailed patho-anatomical observations have not led to the solution of the problems of the etiology and pathogenesis of talipes equinovarus. The reason for such divergence may be that there have been differences of etiology in different cases. But in such clinical and patho-anatomical studies it is difficult especially at late stages to distinguish secondary changes from primary. It is also evident that in congenital deformities different etiological factors may lead to similar structural changes. The orthopedic treatment of deformities however aims at the correction of changes in the musculo-skeletal system or the prevention of their progression or recurrence. Thus information on the nature of the peripheral deforming mechanism may be of great importance in planning effective treatment.

In a study concerning the development and pathogenesis of the experimental dislocation of the hip in the rabbit *Langenskiöld et al* (1964) emphasized some of the basic principles of teratology in the following statement. We know that by altering the environment of the embryo we can produce abnormalities simulating those of genetic origin. We know too that the nature of the alteration or injury is less important in determining the result than its site of action and the stage in embryonic development at which it is applied. Since the development of the skeletal tissue continues after birth it is possible to extend this statement to postnatal developmental events as well. Thus conditions simulating true congenital defects may result from injurious environmental factors affecting the child after the intrauterine period.

Congenital skeletal deformities in humans may have a genetic origin as a rule. But in children we see infections and injuries damaging growing bones and producing deformities similar to those of genetic origin. Observations of foot deformities caused by poliomyelitis and certain

I INTRODUCTION

PURPOSE OF THE INVESTIGATION

Despite the increase in our knowledge of various malformations the etiology of many common deformities such as club-foot and vertical talus remains unknown. Detailed patho-anatomical observations have not led to the solution of the problems of the etiology and pathogenesis of talipes equinovarus. The reason for such divergence may be that there have been difference of etiology in different cases. But in such clinical and patho-anatomical studies it is difficult especially at late stages to distinguish secondary changes from primary. It is also evident that in congenital deformities different etiological factors may lead to similar structural changes. The orthopedic treatment of deformities however aims at the correction of changes in the musculo-skeletal system or the prevention of their progression or recurrence. Thus information on the nature of the peripheral deforming mechanism may be of great importance in planning effective treatment.

In a study concerning the development and pathogenesis of the experimental dislocation of the hip in the rabbit *Langenskiöld et al* (1964) emphasized some of the basic principles of teratology in the following statement. We know that by altering the environment of the embryo we can produce abnormalities simulating those of genetic origin. We know too that the nature of the alteration or injury is less important in determining the result than its site of action and the stage in embryonic development at which it is applied. Since the development of the skeletal tissue continues after birth it is possible to extend this statement to postnatal developmental events as well. Thus conditions simulating true congenital defects may result from injurious environmental factors affecting the child after the intrauterine period.

Congenital skeletal deformities in humans may have a genetic origin as a rule. But in children we see infections and injuries damaging growing bones and producing deformities similar to those of genetic origin. Observations of foot deformities caused by poliomyelitis and certain

patho anatomical studies of congenital foot deformities have given many investigators reason to suppose that soft tissue anomalies in some way cause bone deformity. On this basis it seems reasonable to try to imitate experimentally conditions which have been shown to result from abnormalities of the germ plasm.

Therefore the purpose of the present study was

- to investigate whether it is possible to produce foot deformities in newborn rabbits phenotypically similar to human congenital deformities especially talipes equinovarus deformity by means of various surgical and non surgical soft tissue procedures
- to carry out a detailed anatomic study of deformities produced by these procedures
- to elucidate the peripheral deforming mechanism in congenital foot deformities by comparing observations in humans with experimental results achieved

II REVIEW OF LITERATURE

A TALIPES EQUINOVARUS

1 Etiology

The first etiological theory was that of *Hippocrates* (Kite 1964). He believed that club-foot was the result of intra uterine pressure. This idea has been elaborated with convincing arguments by *Denis Browne* (1933 1936 1967). Many others have returned to the notion that intra uterine position or mechanical factors may be the cause of club foot (*Parker and Schatlock* 1884 *Kelch* 1897 *Nutt* 1925).

Club-foot has also been considered to be secondary to a lesion of the external popliteal nerve caused by pressure at the intra uterine stage (*Hite* 1929). Another neurological theory of the cause of club foot is that it might result from a nerve lesion similar to deformities which result in nerve lesions after birth (*Little* 1839 *Adams* 1873). *Chapman* (1839) wrote "Club-foot originates in the nerves supplying the flexor and extensor muscles of the foot". *Nutt* (1925) also mentioned as one etiological possibility of the cause of the club-foot a nerve anomaly. A primary defect of the spinal cord has also been considered to be the cause of club-foot (*Courviller* 1897 *Dittrich* 1930).

The part played by heredity was stressed by *Aschner* and *Engelmann* in 1928 and by many since. *Compere* (1951) considered hereditary factors leading to neuromuscular imbalance as a cause of club-foot.

Disturbances in the development of striated muscle fibres (*Middleton* 1932) a primary muscular defect (*Smith* 1948) an imbalance of muscles resulting from their hypo- or hypertonicity (*Lombard* 1950 and 1952) a primary muscular imbalance due to dysplasia of the peroneals (*Flinchum* 1953) a relative shortening of degenerating muscle fibres during growth (*Bechtol* and *Mossman* 1950) are muscular changes on which the blame has been laid for the origin of club-foot.

That the activity of the anomalously inserted muscles can lead to foot deformity has been suggested by many authors (*Scherb* 1930 *Stewart* 1951 *Fredenhausen* 1955 *Isclan* 1958 and 1960).

patho anatomical studies of congenital foot deformities have given many investigators reason to suppose that soft tissue anomalies in some way cause bone deformity. On this basis it seems reasonable to try to imitate experimentally conditions which have been shown to result from abnormalities of the germ plasma.

Therefore the purpose of the present study was

- to investigate whether it is possible to produce foot deformities in newborn rabbits phenotypically similar to human congenital deformities especially talipes equinovarus deformity by means of various surgical and non surgical soft tissue procedures
- to carry out a detailed anatomic study of deformities produced by these procedures

The first etiological theory was that of *Hippocrates* (*Hite* 1964). He believed that club-foot was the result of intra uterine pressure. This idea has been elaborated with convincing arguments by *Denis Browne* (1933, 1936, 1967). Many others have returned to the notion that intra uterine position or mechanical factors may be the cause of club foot (*Parker* and *Schatlock* 1854, *Ketch* 1892, *Nutt* 1925).

Club foot has also been considered to be secondary to a lesion of the external popliteal nerve caused by pressure at the intra uterine stage (*Hite* 1929). Another neurological theory of the cause of club foot is that it might result from a nerve lesion similar to deformities which result in nerve lesions after birth (*Little* 1839, *Adams* 1873). *Chapman* (1839) wrote: "Club foot originates in the nerves supplying the flexor and extensor muscles of the foot." *Nutt* (1925) also mentioned as one etiological possibility of the cause of the club foot a nerve anomaly. A primary defect of the spinal cord has also been considered to be the cause of club-foot (*Courtillet* 1897, *Duttrich* 1930).

The part played by heredity was stressed by *Aschner* and *Ingelmann* in 1928 and by many since. *Compere* (1951) considered hereditary factors leading to neuromuscular imbalance as a cause of club foot.

Disturbances in the development of striated muscle fibres (*Middleton* 1932), a primary muscular defect (*Smith* 1945), an imbalance of muscles resulting from their hypo- or hypertonicity (*Lombard* 1950 and 1952), a primary muscular imbalance due to dysplasia of the peroneals (*Flinchum* 1953), a relative shortening of degenerating muscle fibres during growth (*Bechtol* and *Mossman* 1950) are muscular changes on which the blame has been laid for the origin of club foot.

That the activity of the anomalously inserted muscles can lead to foot deformity has been suggested by many authors (*Scherb* 1930, *Stewart* 1951, *Fredenhagen* 1955, *Inclan* 1958 and 1960).

Wiley (1959) thought the primary cause of club foot was an extrinsic factor maintaining the foot in a deformed position and causing deficiencies in the growth of the leg muscles

According to one theory the cause of club foot was developmental inhibition or arrested development at the embryological stage when muscles tendons and joints develop (Bessel-Hagen 1889 Ketch 1892 Bohm 1929 Schinz et al 1952 Fripp and Shaw 1967)

The hypothesis that club foot is due to congenital dislocation of the head of the talus has been advanced by Brockman (1930 1937) Also Reimann (1967) believed that congenital club foot is a deformity of local nature caused by primary dislocation between the tarsal navicular and the head of the talus during fetal life

Mesenchymal dysplasia in the medial part of the foot has been considered the mechanism of club foot (Keith 1940) Changes in connective tissues have also been suggested as the cause of club foot by others (Scheel 1951 Ode 1952)

2 Pathological anatomy

Patho anatomical observations of foot deformities have been made at autopsy since antiquity and operative examination has become common during the last few decades But dissection of fetal and immediately postnatal club foot in order to determine primary changes of the intra uterine period has not been seriously undertaken until very recent times After the first few years of life secondary adaptive changes lead to a confusing picture

Formerly the pathology of congenital skeletal deformities was studied almost entirely from the bone deformity point of view and the skeletal changes were considered primary Nowadays however the belief is widespread that pathological changes in the muscle-tendon apparatus precede and even initiate bone changes

a) Bone changes

After examining the bones of children with club foot some 165 years ago Scarpa believed that the deformity was due to medial twisting of the navicular cuboid and calcaneus in relation to the talus The talus itself was considered normal in shape and position Muscle abnormalities were considered secondary Adams (1873) asserted that the essential change involved in idiopathic club foot occurred in the tarsus He found the principal deformity in the talus particularly in the neck and head of the

talus Scudder (1887) noted that the neck of the astragalus turned inward instead of being straight. In the 19th century there were several German accounts of club-foot dissection with particular elucidation of bony changes (Huetler 1863 Kocher 1878 etc.) Similar work was done by Parker and Schatlock (1854) who noted talar deformity as did the Russian Sherbunenko (1899).

Burrell (1893) found no important muscle changes in a seven month fetus with a club foot. He found bone changes however and said: "The astragalus of the deformed foot was small and its neck short. The outer part of the articular surface of the deformed astragalus as it articulated with the scaphoid was distinctly diminished in size."

Nichols (1897) in his dissection of a stillborn child with club foot noted only directional changes and shortening in the tendons of tibialis anterior posterior and gastrocnemius. He stated: "The deformity of the foot in cases of congenital equinus is due essentially to an alteration in the shape of the bones of the foot. The greatest and most important abnormalities are the obliquity of the facets and the change in the shape of the bones which enter into the information of the midtarsal joint that is the astragalus and the os calcis posteriorly and the scaphoid and cuboid anteriorly. All the bones are altered."

Until quite recently in fact the main emphasis in dissection reports was placed on bony changes in congenital foot deformity. This was the case in dissections performed by Elmslie (1910) and Pfannen (1910). Bohm (1935) also noted that the soft tissues were normal and the equinovarus foot depended upon serious deformities of the talus and calcaneus. In their publications and monographs Kren (1927) Mau (1927) Virchow (1933) Debrunner (1936) Bernbeck (1950 1955) and Schlicht (1963) have described in detail the bony changes of talipes equinovarus with emphasis on changes of shape in the talus and its joint surfaces to which other tarsal bones (cuboid navicular and calcaneus) adapt themselves with lesser changes.

Three careful studies of the anatomy of club-foot in fetuses and still born children have been published very recently. Irani and Sherman (1963) examined eleven cases of club-foot and three calcaneo-valgus foot. Their conclusions were: "In idiopathic club foot there are no primary abnormalities of vessels nerves muscles or tendon insertions. Only the anterior part of the talus is always abnormal. The anterior part of the calcaneus is usually abnormal but much less so and to variable degree. These deviations probably result from a defective cartilaginous anlage which is dependent upon a primary germ plasm defect." Settle (1963)

presented his anatomical findings from the dissection of sixteen infantile club-feet. Anatomical abnormalities were surprisingly uniform. He writes: "congenital talipes equinovarus is a composite deformity involving all tissues of the foot. There are no simple or isolated defects such as contracted bands or peroneal muscle atrophy, but each tissue conforms to the equinus and varus position. The major bone deformity resides in the talus. Its neck and articular surface for the navicular deviate to face medially and plantarward. Congenital club foot is a primary developmental deformity of the hind part of the foot." *Reimann* (1967) presented the dissection material of six cases comprising fetuses still borns and persons with club foot who had died. Her conclusions were:

Gross and histological studies of the spinal cord and nerve roots including ganglion cell counts disclosed no abnormality in the club foot cases. Histological study of muscles showed no signs of neurogenous atrophy. Histological study of the muscles showed normal muscles. Microscopically the average diameter of the muscle fibres was diminished. Histologically the vessels have proved normal. Skeletal changes have been a constant finding consisting of dysplasia and changes in shape mostly affecting the talus. The skeletal changes are considered to be secondary.

b) Soft tissue changes

Little (1839) was the first to assert that uncoordinated muscle activity or abnormal tendon insertions might be the cause of club foot and mentions the notion of Hippocrates that muscles maintain the clubfoot. *Mackie et al* (1820) (quoted by *Little*) and *Tourtual* (1832) had made earlier observations on muscles in this connection.

Adams (1854-1855) described the dissection of immediately post natal cases of club foot and discovered anomalies in the gastrocnemius, the tibialis anterior and the tibialis posterior muscles which were very tense and possibly hypertrophied. All three muscle bellies were shortened. The extensor digitorum longus muscle was very small and microscopically degenerate. In another case he found several tendinous abnormalities. Nevertheless he considered soft tissue changes to be secondary and was convinced that the talus changes he had found were primary.

Jon Loubman (1863) also described changes in the muscles of club foot and noted small peroneal muscles and a small extensor digitorum communis muscle.

Bissell (1898) studied the muscles of the equinovarus feet of an infant and noted that the tibialis anterior and posterior tendons had

shortened and moved inwards. Like many other investigators however he was more deeply concerned with detailed description of bone changes especially in the talus.

Elmslie (1920) discussed the anatomy of the club-foot. He wrote that the chief factor of the deformity was a displacement of the bones and that the importance of the tendons in maintaining a deformity had been much exaggerated. But he also said: "Doubtless the tendons of the *tibialis anticus* and *posticus* and *tendo Achillis* have a considerable part in the original production of the deformity."

Dittrich (1930) published the results of a dissection of an infant with bilateral club-foot and came to the conclusion that "the position and form of the various components of the foot are secondary to changes in the soft tissues which control them."

Middleton (1932) studied the pathological anatomy of congenital anomalies and assembled material which included congenital tibial hypoplasia and *arthrogryposis multiplex congenita*. He suggested the imperfect development of striated muscle as a possible cause of certain congenital deformities of the extremities.

Mau (1938) made an examination of three fetuses with club-foot and other congenital abnormalities. In muscles he found macroscopically nothing of note but histologically there was a loss of striation. He considered this secondary to myelodysplasia. He noted changes in each muscle of his histological specimen and could not attribute the deformity to any particular muscle.

Scherb (1930) also noted anomalies in club foot muscles. In operations he often noticed an attachment of the *peroneus brevis* muscle to the cuboid instead of the usual attachment to the fifth metatarsal. This he asserted "was the cause of a depression of the lateral edge of the foot and a relative increase of supination power due to the abductive effect of the *peroneus brevis* muscle on the metatarsal plate decreased." Similar changes in the lateral tendinous region have been noted by *Debrunner* (1957) and also by *Fredenhagen* (1954).

Geckro and *Mossman* (1950) studied embryonic club foot and observed changes in muscular development, some cases being more imperfectly developed in the histological sense. Thus the authors maintained "was the cause of the muscular imbalance of club-foot."

Steinert (1951) presented his findings from the dissection of one stillborn and twenty operated patients. He found several abnormalities of tendon insertion but most common was the unusual attachment of the *Achilles* tendon to the medial side of the *tuber calcanei*. His findings were in full

presented his anatomical findings from the dissection of sixteen infantile club feet. Anatomical abnormalities were surprisingly uniform. He writes: "congenital talipes equinovarus is a composite deformity involving all tissues of the foot. There are no simple or isolated defects, such as contracted bands or peroneal muscle atrophy, but each tissue conforms to the equinus and varus position. The major bone deformity resides in the talus. Its neck and articular surface for the navicular deviate to face medially and plantarward. Congenital club foot is a primary developmental deformity of the hind part of the foot." *Reiman* (1967) presented the dissection material of six cases comprising fetuses, still-borns and persons with club foot who had died. Her conclusions were:

Microscopically the average diameter of the muscle fibres was diminished. Histologically the vessels have proved normal. Skeletal changes have been a constant finding consisting of dysplasia and changes in shape mostly affecting the talus. The skeletal changes are considered to be secondary.

b) Soft tissue changes

Little (1839) was the first to assert that uncoordinated muscle activity or abnormal tendon insertions might be the cause of club foot and mentions the notion of Hippocrates that muscles maintain the clubfoot. *Mackeever* (1820) (quoted by *Little*) and *Tourtual* (1832) had made earlier observations on muscles in this connection.

Adams (1854—1855) described the dissection of immediately post-natal cases of club foot and discovered anomalies in the gastrocnemius, the tibialis anterior and the tibialis posterior muscles which were very tense and possibly hypertrophied. All three muscle bellies were shortened. The extensor digitorum longus muscle was very small and microscopically degenerate. In another case he found several tendinous abnormalities. Nevertheless he considered soft tissue changes to be secondary and was convinced that the talus changes he had found were primary.

Von Iolkmann (1863) also described changes in the muscles of club-foot and noted small peroneal muscles and a small extensor digitorum communis muscle.

Bissell (1888) studied the muscles of the equinovarus feet of an infant and noted that the tibialis anterior and posterior tendons had

shortened and moved inwards. Like many other investigators however he was more deeply concerned with detailed description of bone changes especially in the talus.

Elmslie (1920) discussed the anatomy of the club-foot. He wrote that the chief factor of the deformity was a displacement of the bones and that the importance of the tendons in maintaining a deformity had been much exaggerated. But he also said: "Doubtless the tendons of the *tibialis anticus* and *posticus* and *tendo Achillis* have a considerable part in the original production of the deformity."

Dittrich (1930) published the results of a dissection of an infant with bilateral club-foot and came to the conclusion that "the position and form of the various components of the foot are secondary to changes in the soft tissues which control them."

Middleton (1932) studied the pathological anatomy of congenital anomalies and assembled material which included congenital tibial hypophysis and *arthrogryposis multiplex congenita*. He suggested the imperfect development of striated muscle as a possible cause of certain congenital deformities of the extremities.

Vau (1938) made an examination of three fetuses with club-foot and other congenital abnormalities. In muscles he found macroscopically nothing of note but histologically there was a loss of striation. He considered this secondary to *myelodysplasia*. He noted changes in each muscle of his histological specimen and could not attribute the deformity to any particular muscle.

Scherb (1930) also noted anomalies in club foot muscles. In operations he often noticed an attachment of the *peroneus brevis* muscle to the cuboid instead of the usual attachment to the fifth metatarsal. This he asserted was the cause of a depression of the lateral edge of the foot and a relative increase of supination power due to the abductive effect of the *peroneus brevis* muscle on the metatarsal plate decreased. Similar changes in the lateral tendinous region have been noted by Debrunner (1937) and also by Fredenhagen (1934).

Bechtol and Vossman (1930) studied *embryonic club foot* and observed changes in muscular development, some cases being more imperfectly developed in the histological sense. Thus the authors maintained was the cause of the muscular imbalance of club foot.

Stewart (1931) presented his findings from the dissection of one stillborn and twenty operated patients. He found several abnormalities of tendon insertion but most common was the unusual attachment of the *Achilles tendon* to the medial side of the *tuber calcanei*. His findings were in full

agreement with the results presented earlier by Scherb. In 1954 Penners published similar insertion anomalies noted in operated patients. They occurred in Achilles tendon insertions in the tibialis anterior and extensor hallucis longus tendons in the plantaris muscle in the insertion of the tibialis posterior tendon and in the plantar fascia.

Flinchum in 1953 published the results of his dissection of a club-foot in a six and a half month infant. He found an insertion anomaly of the Achilles tendon, a large tibialis anterior muscle and small peroneal muscles. The tibialis posterior muscle was normal compared to the standard of a healthy foot. The author considered bone changes secondary resulting from muscular imbalance.

Wiley (1959) gathered material in six cases of club-foot from post mortem examinations performed on infants. He noted that the bellies of the long muscles were shorter and thinner and commented. In the severe cases abnormal musculature was noted throughout the long muscles. In talipes equinovarus the principal muscles affected were the gastrocnemius and soleus, the tibialis posterior and the tibialis anterior in that order. The cause of these muscle changes in his opinion was an extrinsic factor maintaining the foot in a deformed position and causing growth deficiencies in the long muscle.

B VERTICAL TALUS

The congenital flat foot deformity connected with the vertical position of the talus received no attention in the literature until this century. The vertical position had evidently remained unnoticed and vertical talus cases had been discussed in connection with ordinary flat foot cases. It was the development of the X ray technique which made a consideration of the various forms of flat foot possible.

The first complete radiological, anatomical and pathological study of extreme flat foot with vertical talus dates from 1914 (*Henken*). Numerous publications followed in which the deformity was described. They were mainly from continental Europe in the period 1920-40. All authors noted the special features of the deformity. These are clinically: convexity of the sole, deviation into valgus of the posterior part of the foot, abduction and dorsiflexion of the forepart of the foot and radiographically, the vertical or oblique position of the talus.

There have been divergent opinions on the nature of the deformity, however, some considering it a specific congenital malformation (*Chrysospathes* 1938) and others not considering it a morbid entity (*Ombredanne*

1928) It has been recognized by most authors recently as an individual entity (*Herndon and Heyman 1963*) The latter used the term congenital convex pes valgus which was first used in 1939 by *Lamy and Weissman* who list nine other terms in use The terms vertical talus or congenital talonavicular dislocation or subluxation are recent additions All these reflect different points of view in the interpretation of this deformity

As with the etiology and pathology of talipes equinovarus deformity there are a great variety of corresponding theories on the etiology and pathogenesis of congenital flat foot and congenital vertical talus deformity They can be divided into exogenic or extrinsic and endogenic or intrinsic theories

Many have believed congenital flat foot is an exogenic malformation caused by intra uterine pressure (*Henke 1859 Kustner 1880 Joachimsthal 1903 Lange 1912 Henken 1914 Krukenberg 1934-1935 Denis Browne 1966 Harrold 1967*) According to *Murk-Jansen* (quoted by *Spiro 1934-1935*) pressure arises from a deficiency of amnion *Chrysospathes* (1938) thought that pressure of the tibia against the tarsal bones in the early embryonic stage with the foot in dorsiflexion would cause deformity

Many factors have been suggested which support the theory of endogenic origin The deformity is often accompanied by other congenital malformations such as congenital luxation of the hip club foot arthrogryposis spina bifida congenital kyphosis hypospadias and microcephaly Some have found evidence of heredity in this condition (*Ischner and Engelmann 1928*) Also congenital talus verticalis has certain features in common with certain stages of the normal embryogenic development of the foot Various authors consider that disturbed development of the bones of the foot is the primary reason for the deformity as in club foot

Franke (1901) considered disturbances of muscle balance to be the cause of congenital flat foot He asserted that the insertion of the tibialis anterior had moved from the plantar to the dorsal side and that its supinatory effect was thus eliminated *Braus* (quoted by *Lamy and Weissman 1939*) has noted in 50 per cent of congenital flat foot cases that the supinatory effect of the tibialis anterior is lacking because of insertion variation According to *Lamy and Weissman* Man pursuing the same line of thought assumed that a spinal lesion could cause a predominance of peroneal muscle action at a certain stage of fetal development leading to a valgus position of the foot

Some have surmised that abnormal congenital laxity of muscles and ligaments is the reason for congenital convex pes valgus (*Hagenbach Burckhardt* 1907 *Hackenbroch* 1924)

Some connect the changes with spina bifida occulta (*Peltesohn* 1920 *Beck* 1922 *Hackenbroch* 1924 *Spiro* 1934-1935)

Fuchs (quoted by *Spiro*) speaks of myelodysplastic changes which may sometimes be merely microscopic

Bohm (1932) has shown that at the end of the second fetal month and the beginning of the third the long axis of the talus is the same as that of the leg and the position of the bones of the foot corresponds most closely to that seen in congenital vertical talus. It is thus suggested that the deformity is a cessation of development at that stage (*Böhm* 1932 *Spiro* 1934-1935) *Mau* (1930) has suggested that the primary cause of this arrested development is a lesion of the spinal cord and that the foot deformity is secondary

Lamy and *Weissman* (1939) state that all explanations of congenital pes valgus are far from satisfactory and the cause is still to be found. It should be sought among endogenous factors however since external factors only occasionally intervene. The role of the nervous system appears to be the most important. This is their opinion of the pathogenesis of club foot in general

Hark (1950) emphasized two facts concerning the etiology: one is the multiplicity of other deformities accompanying rocker foot and the other is the occurrence of only one case of spina bifida in his series. He believes that spina bifida is merely one manifestation of a developmental disturbance which may include rocker foot as well as other deformities

Osmond Clarke (1956) suggested the possibility that in the early intra-uterine life the foot with vertical talus has moved its position laterally in relation to the talus. The thought appealed to him that this may be an extreme form of congenital talipes valgus and that vertical talus is a subluxation of the talonavicular joint as in club foot but in the opposite direction

Herndon and *Heyman* (1963) are inclined to believe that congenital convex pes valgus is related to an embryological fault during the first three months of pregnancy and that the deformity is closely akin to club foot in etiology

Storen (1967) said: Observations made at operation support those made during closed reduction. The vertical position of talus is secondary to the subluxation seen in Chopart's joint which is in a great deal believed to be the primary event

C EXPERIMENTAL PRODUCTION OF SKELETAL MALFORMATIONS

The etiology of congenital defects in human beings is virtually unknown and evidently both genetic and environmental influences are involved (Halter 1965 Saven and Rapola 1969) For many years congenital anomalies were generally assumed to be wholly due to defects of the genes chromosomes and germ plasma Genetic considerations have tended to overshadow the importance of the environmental influences (Ingalls 1955) However the association of developmental anomalies with epidemics of rubella noted first in Australia by Gregg (1941) and attributed to maternal infection in the early months of pregnancy by Siran (1949) demonstrates clearly enough that changes in the genome cannot always be invoked as the cause of congenital abnormalities Systematic studies of the congenital anomalies demonstrates that part of them are hereditary genotypic but also that environmental factors have teratogenic influence The recent appearance of newborn babies with malformed limbs due to maternal ingestion of thalidomide as a tranquilizing drug during pregnancy has revealed the sensitivity of the fetus to these teratogenic factors (Len and Knapp 1964)

Experimental teratology has made great progress in the last few years and many excellent articles have been written on the experimental production of malformations (Fraser 1964 Salgeher and W olff 1964 Saxen and Rapola 1969) The list of exogenous factors causing skeletal malformations in experimental animals is long and includes mechanical injuries hypoxia ionizing radiation a great variety of chemical compounds dietary deficiencies hormonal factors virus inoculation etc Such factors may act on a genetically normal embryo causing different skeletal anomalies but several examples have been described in which synergistic effect with a mutant gene has been demonstrated (Fraser Walker and Trasler 1957 Landauer 1965 Dagg 1967) Only a few pioneering experiments in this field have been chosen for discussion and reader is referred to recent articles where the problem has been dealt with in greater detail

Earlier mechanical factors were generally considered to be an important cause of skeletal anomalies Browne (1936 1967) has presented a vast material on deformities of mechanistic causation Trasler Walker and Fraser (1956) have experimentally produced congenital malformations in mice by amniotic sac puncture

Hypoxia is a teratogenic factor Romanoff (1930) found that hypoxia caused anomalies in the chick embryos Both Ingalls Curley and Prindle

Some have surmised that abnormal congenital laxity of muscles and ligaments is the reason for congenital convex pes valgus (*Hagenbach Burckhardt* 1907 *Hackenbroch* 1924)

Some connect the changes with spina bifida occulta (*Pellessohn* 1920 *Beck* 1922 *Hackenbroch* 1924 *Spiro* 1934—1935)

Fuchs (quoted by *Spiro*) speaks of myelodysplastic changes which may sometimes be merely microscopic

Bohm (1932) has shown that at the end of the second fetal month and the beginning of the third the long axis of the talus is the same as that of the leg and the position of the bones of the foot corresponds most closely to that seen in congenital vertical talus. It is thus suggested that the deformity is a cessation of development at that stage (*Bohm* 1932 *Spiro* 1934—1935). *Mau* (1930) has suggested that the primary cause of this arrested development is a lesion of the spinal cord and that the foot deformity is secondary.

Lamy and Weissman (1939) state that all explanations of congenital pes valgus are far from satisfactory and the cause is still to be found. It should be sought among endogenous factors however since external factors only occasionally intervene. The role of the nervous system appears to be the most important. This is their opinion of the pathogenesis of club foot in general.

Hark (1950) emphasized two facts concerning the etiology: one is the multiplicity of other deformities accompanying rocker foot and the other is the occurrence of only one case of spina bifida in his series. He believes that spina bifida is merely one manifestation of a developmental disturbance which may include rocker foot as well as other deformities.

Osmond Clarke (1956) suggested the possibility that in the early intra uterine life the foot with vertical talus has moved its position laterally in relation to the talus. The thought appealed to him that this may be an extreme form of congenital talipes valgus and that vertical talus is a subluxation of the talonavicular joint as in club foot but in the opposite direction.

Herndon and Heyman (1963) are inclined to believe that congenital convex pes valgus is related to an embryological fault during the first three months of pregnancy and that the deformity is closely akin to club foot in etiology.

Storen (1967) said: Observations made at operation support those made during closed reduction. The vertical position of talus is secondary to the subluxation seen in Choparts joint which is in a great deal believed to be the primary event.

C EXPERIMENTAL PRODUCTION OF SKELETAL MALFORMATIONS

The etiology of congenital defects in human beings is virtually unknown and evidently both genetic and environmental influences are involved (Kalter 1965, Saxén and Rapola 1969). For many years congenital anomalies were generally assumed to be wholly due to defects of the genes, chromosomes and germ plasma. Genetic considerations have tended to overshadow the importance of the environmental influences (Ingalls 1955). However the association of developmental anomalies with epidemics of rubella noted first in Australia by Gregg (1941) and attributed to maternal infection in the early months of pregnancy by Swan (1949) demonstrates clearly enough that changes in the genome cannot always be invoked as the cause of congenital abnormalities. Systematic studies of the congenital anomalies demonstrates that part of them are hereditary, genotypic but also that environmental factors have teratogenic influence. The recent appearance of newborn babies with malformed limbs due to maternal ingestion of thalidomide as a tranquilizing drug during pregnancy has revealed the sensitivity of the fetus to these teratogenic factors (Len and Knapp 1962).

Experimental teratology has made great progress in the last few years and many excellent articles have been written on the experimental production of malformations (Fraser 1964, Salgeber and Wolff 1964, Saxén and Rapola 1969). The list of exogenous factors causing skeletal malformations in experimental animals is long and includes mechanical injuries, hypoxia, ionizing radiation, a great variety of chemical compounds, dietary deficiencies, hormonal factors, virus inoculation etc. Such factors may act on a genetically normal embryo causing different skeletal anomalies but several examples have been described in which synergistic effect with a mutant gene has been demonstrated (Fraser, Walker and Trasler 1957, Landauer 1965, Dagg 1967). Only a few pioneering experiments in this field have been chosen for discussion and reader is referred to recent articles where the problem has been dealt with in greater detail.

Earlier mechanical factors were generally considered to be an important cause of skeletal anomalies. Browne (1936, 1967) has presented a vast material on deformities of mechanical causation. Trasler, Walker and Fraser (1956) have experimentally produced congenital malformations in mice by amniotic sac puncture.

Hypoxia is a teratogenic factor. Romanoff (1930) found that hypoxia caused anomalies in the chick embryos. Both Ingalls, Curley and Prindle

Some have surmised that abnormal congenital laxity of muscles and ligaments is the reason for congenital convex pes valgus (*Hagenbach Burckhardt* 1907 *Hackenbroch* 1924)

Some connect the changes with spina bifida occulta (*Pellessohn* 1920 *Beck* 1922 *Hackenbroch* 1924 *Spiro* 1934—1935)

Fuchs (quoted by *Spiro*) speaks of myelodysplastic changes which may sometimes be merely microscopic

Bohm (1932) has shown that at the end of the second fetal month and the beginning of the third the long axis of the talus is the same as that of the leg and the position of the bones of the foot corresponds most closely to that seen in congenital vertical talus. It is thus suggested that the deformity is a cessation of development at that stage (*Bohm* 1932 *Spiro* 1934—1935) *Mau* (1930) has suggested that the primary cause of this arrested development is a lesion of the spinal cord and that the foot deformity is secondary

Lamy and *Weissman* (1939) state that all explanations of congenital pes valgus are far from satisfactory and the cause is still to be found. It should be sought among endogenous factors however, since external factors only occasionally intervene. The role of the nervous system appears to be the most important. This is their opinion of the pathogenesis of club foot in general

Hark (1950) emphasized two facts concerning the etiology: one is the multiplicity of other deformities accompanying rocker foot and the other is the occurrence of only one case of spina bifida in his series. He believes that spina bifida is merely one manifestation of a developmental disturbance which may include rocker foot as well as other deformities

Osmond Clarke (1956) suggested the possibility that in the early intra-uterine life the foot with vertical talus has moved its position laterally in relation to the talus. The thought appeared to him that this may be an extreme form of congenital talipes valgus and that vertical talus is a subluxation of the talonavicular joint as in club foot but in the opposite direction

Herndon and *Heyman* (1963) are inclined to believe that congenital convex pes valgus is related to an embryological fault during the first three months of pregnancy and that the deformity is closely akin to club foot in etiology

Storen (1967) said: Observations made at operation support those made during closed reduction. The vertical position of talus is secondary to the subluxation seen in Chopart's joint which is in a great deal believed to be the primary event

C EXPERIMENTAL PRODUCTION OF SKELETAL MALFORMATIONS

The etiology of congenital defects in human beings is virtually unknown and evidently both genetic and environmental influences are involved (*Kalter 1965 Saxon and Rapola 1969*). For many years congenital anomalies were generally assumed to be wholly due to defects of the genes chromosomes and germ plasma. Genetic considerations have tended to overshadow the importance of the environmental influences (*Ingalls 1955*). However the association of developmental anomalies with epidemics of rubella noted first in Australia by *Gregg (1941)* and attributed to maternal infection in the early months of pregnancy by *Siran (1949)* demonstrates clearly enough that changes in the genome cannot always be invoked as the cause of congenital abnormalities. Systematic studies of the congenital anomalies demonstrates that part of them are hereditary genotypic but also that environmental factors have teratogenic influence. The recent appearance of newborn babies with malformed limbs due to maternal ingestion of thalidomide as a tranquilizing drug during pregnancy has revealed the sensitivity of the fetus to these teratogenic factors (*Len and Knapp 1962*).

Experimental teratology has made great progress in the last few years and many excellent articles have been written on the experimental production of malformations (*Fraser 1964 Salgeher and Woff 1964 Saxon and Rapola 1969*). The list of exogenous factors causing skeletal malformations in experimental animals is long and includes mechanical injuries hypoxia ionizing radiation a great variety of chemical compounds dietary deficiencies hormonal factors virus inoculation etc. Such factors may act on a genetically normal embryo causing different skeletal anomalies but several examples have been described in which synergistic effect with a mutant gene has been demonstrated (*Fraser Walker and Trasler 1957 Landauer 1965 Dagg 1967*). Only a few pioneering experiments in this field have been chosen for discussion and reader is referred to recent articles where the problem has been dealt with in greater detail.

Earlier mechanical factors were generally considered to be an important cause of skeletal anomalies. *Brown (1936 1967)* has presented a vast material on deformities of mechanistic causation. *Trasler Walker and Fraser (1956)* have experimentally produced congenital malformations in mice by amniotic-sac puncture.

Hypoxia is a teratogenic factor. *Romanoff (1930)* found that hypoxia caused anomalies in the chick embryos. Both *Ingalls Curley and Prindle*

(1952) and later *Degenhardt* and *Knoche* (1959) have published detailed material on the skeletal defects in the offspring of mothers subjected to low oxygen pressures

Ionizing radiation has been used for the experimental provocation of congenital deformities. The first experiments on mammals were carried out in pregnant rabbits by *Hippel* in 1905. In 1920—29 *Bagg* published his important studies. He investigated the effect of X rays, radium emanation and injections of radio active solutions on the development of mice, rats and dogs. The most constant lesions occurred in the head region of embryos. There were also abnormalities of the limbs, various forms of club foot, syndactylism, hypodactylism, congenital amputations and polydactylism. Later *Warkany* and *Schraffenberger* (1947) in rats and *Russel* and *Russel* (1954) in mice produced primarily skeletal anomalies by X-ray irradiation.

Chemoteratogenesis the production of malformations by means of chemical substances has after the thalidomide disaster attracted much interest. Many active teratogens, both naturally occurring and artificially produced, have since been described. However, as early as 1921 *Stockard* published a classic study in which he succeeded in reproducing malformations by means of chemical agents. The work of *Angel* and *Lallemand* (1942) has contributed considerably to the development of experimental teratology. They succeeded in producing malformations of chick embryos by eserine sulphate and sulphonamide. Since then a great variety of chemical compounds have been tested for their teratogenic action, and in most cases a suitable combination of dose and animal species have yielded positive results. As regards human development, proven chemical teratogens are however few (*Cohen* 1966). The thalidomide accidents prompted a large number of investigators to test thalidomide in various animal species. In mice and rabbits it had a teratogenic effect. The first experiments were carried out by *Giroud*, *Tuchmann-Duplessis* and *Mercier-Parot* (1962). With regard to the limbs, the most common findings were malformations of the club foot type. *Drachman* and *Coulombre* (1962) induced club feet and arthrogryposis curarizing chick fetuses.

Dietary deficiencies have a teratogenic effect. The first research on vitamin deficiency was carried out by *Hale* (1933). He produced eye anomalies in pigs by vitamin A deficiency. *Warkany* and *Nelson* (1940) used the deficiency of riboflavin in the mother's diet to induce experimentally skeletal malformations like many other anomalies. Deficiency

of folic acid panthotemic acid and vitamin E have also been used to produce skeletal anomalies cleft palate club-foot etc

Hormonal factors can also induce experimental malformations Insulin has a strong teratogenic effect on the limb in the chick embryo (Landauer 1945) Very interesting studies to orthopedic surgery were carried out by Duraiswami (1952) who induced congenital skeletal defects in chick embryos also by insulin Using certain pituitary preparations Jost (1953) obtained degeneration of the extremities in the rat fetus Cortisone has been used as a teratogenic agent by many Hicks (1954) provoked among other defects skeletal anomalies by large cortisone doses in mice The investigations of Walker and Fraser (1956 1957) who induced cleft palate deformity by cortisone both in mice and rats are classical

In experimental teratology many other environmental agents such as virus infection have been used to produce congenital anomalies By mean of influenza A virus in chick embryos Hamburger and Habel (1947) provoked a typical anomaly microcephaly and Fern and Kilham (1964) induced congenital anomalies in hamster with H 1 virus

Intra uterine manipulations have also been used in experimental teratology Some recent experiments in which embryos have been treated locally *in utero* may prove very important Schinckel and Ferguson (1963) performed skin graftings on fetal lambs for studying the development of the immune system In 1964 Spencer and Peltier reported their attempts utilizing *in utero* surgical procedures to produce a deformity in the fetal rabbit extremity By means of a silk suture a fore foot was placed in a moderate degree of flexion and ulnar deviation On the day of delivery the suture was removed from the extremity and the rabbit observed for deformity

Postnatal experimental production of skeletal deformities by transection of muscles and ligaments by denervation of muscles and by bone or joint procedures has been described in scoliosis dislocation of hip etc (Schuarmann and Miles 1945 Langenskiöld Sarpio and Michelsson 1960 Michelsson 1965) However I have not found in the literature a single such report concerning experimental production of limb deformity

(1952) and later *Degenhardt* and *Knoche* (1959) have published detailed material on the skeletal defects in the offspring of mothers subjected to low oxygen pressures

Ionizing radiation has been used for the experimental provocation of congenital deformities. The first experiments on mammals were carried out in pregnant rabbits by *v Hippel* in 1905. In 1920—29 *Bagg* published his important studies. He investigated the effect of X-rays, radium emanation and injections of radio active solutions on the development of mice, rats and dogs. The most constant lesions occurred in the head region of embryos. There were also abnormalities of the limbs, various forms of club foot, syndactylism, hypodactylism, congenital amputations and polydactylism. Later *Warkany* and *Schraffenberger* (1947) in rats and *Russel* and *Russel* (1954) in mice produced primarily skeletal anomalies by X-ray irradiation.

Chemoteratogenesis the production of malformations by means of chemical substances has after the thalidomide disaster attracted much interest. Many active teratogens, both naturally occurring and artificially produced, have since been described. However, as early as 1921 *Stockard* published a classic study in which he succeeded in reproducing malformations by means of chemical agents. The work of *Ancel* and *Lallemand* (1942) has contributed considerably to the development of experimental teratology. They succeeded in producing malformations of chick embryos by eserine sulphate and sulphonamide. Since then a great variety of chemical compounds have been tested for their teratogenic action, and in most cases a suitable combination of dose and animal species have yielded positive results. As regards human development, proven chemical teratogens are however few (*Cahen* 1966). The thalidomide accidents prompted a large number of investigators to test thalidomide in various animal species. In mice and rabbits it had a teratogenic effect. The first experiments were carried out by *Giroud*, *Tuchmann-Duplessis* and *Mercier-Parot* (1962). With regard to the limbs, the most common findings were malformations of the club foot type. *Drachman* and *Coulombre* (1962) induced club feet and arthrogryposis curarizing chick fetuses.

Dietary deficiencies have a teratogenic effect. The first research on vitamin deficiencies was carried out by *Hale* (1933). He produced eye anomalies in pigs by vitamin A deficiency. *Warkany* and *Nelson* (1940) used the deficiency of riboflavin in the mother's diet to induce experimentally skeletal malformations like many other anomalies. Deficiency

FIG X rays in the lateral projection of the normal foot of a man (top) and of a rabbit (bottom) General skeletal structure and relative positions of bones are strikingly similar

B ANATOMY OF THE FOOT OF THE RABBIT COMPARED WITH THE HUMAN FOOT

The human foot is unlike any other. It is the most distinctly human part of the whole of man's anatomical make up. It is by his feet that man is distinguished from all other members of the animal kingdom (Jones 1944)

Despite this, however, there are remarkable resemblances between the hind feet of quadrupeds and the human foot. The resemblance is of course greatest in anthropoid apes, but the use of such large and expensive animals in the study of foot deformities would present difficulties if a sufficiently large material were to be obtained. In many other four

III MATERIAL AND METHODS

A EXPERIMENTAL ANIMALS

The present study is based on the results of operations on 402 growing rabbits. Approximately 75-100 growing rabbits were used in preliminary experiments and are not included in the results. The rabbits were operated on at the age of four to twenty-eight days, most of them being six to seven days old at operation.

FIG. 1. X rays in the dorsoplantar projection of the normal foot of a rabbit and of a man. General skeletal structure and relative positions of tarsal bones are strikingly similar. The rabbit has four metatarsals and four digits (the first row is missing).

Another method of producing the effect of deformity corresponding to contractures in the periphery was considered. The leg muscles including the gastrocnemius and soleus muscles were fixed with nylon thread through a hole bored through the tibia at its halfway point. It was expected that the muscles would thus be hampered in growth and normal function with resulting constriction and foot deformity. But this too was not wholly successful. The muscle evidently either stretched or grew but while attached was able to adapt itself to the growth of the bones so that no true deformities occurred. A possible explanation may be found in the tests performed by Lange (1929). In a series of experimental rabbits the Achilles tendon and one third to one-half of the belly of the gastrocnemius were excised. A silk thread connected the remaining muscle to the calcaneus with approximately normal tension. Regeneration of muscle started down the thread in eight weeks and had the appearance of normal muscle and tendon.

Tendon fixation or tenodesis was the next method to be tried for provocation of foot deformity. The Achilles tendon which is very strong in rabbits as it is in humans could as a rule be fixed successfully to the tibia. This fixation maintained the calcaneus in a position of plantar flexion and the Achilles tendon could not adapt itself to the growth of the bones. According to Haines (1932) a tendon under tension is unable to increase its length. But it proved technically impossible to achieve this fully with the very thin and muscular tendons of the tibialis anterior and the extensor digitorum longus at the front of the leg of a rabbit. An attempt was therefore made to cause imbalance of muscle power on this side by muscle-tendon transections and transection of the ligamentum transversum cruris. By this means it was also thought possible to bring about changes in the direction of action of the muscles. Observations obtained from paralytic deformities such as those seen in poliomyelitis were considered when planning the experiments. But over a year's work on more than 75 rabbits had been done before a method of operation was evolved which brought about a progressive deformity in the rabbit resembling the talipes equinovarus deformity in man (Ritsila 1964).

D TECHNIQUE

1 General operative technique

The operations were performed under aseptic conditions on the left leg under local anaesthesia (0.25% Xylocain exatrine®) while the right leg was left intact as a control. Longitudinal ventral and dorsal skin incisions

footed plantigrades such as the rabbit moreover there is a basic structure of the foot which conspicuously resembles that found in humans. In particular the structure of tarsal bones and their anatomical interrelation are almost similar. The rabbit's foot is admittedly flatter while the metatarsals and toes are comparatively long and the fore foot has only four metatarsals and digits (Figs 1 and 2). But the skeletal age at birth and soon afterwards is almost the same in humans and rabbits as *Heikel* (1960) has noted. Similarities in leg muscles and other soft tissues are also striking as the study of the anatomy of the rabbit has verified (*Krause* 1884). Hence the young rabbit seems to be a suitable laboratory animal for experiments involving imitation of human foot deformities.

C. DEVELOPMENT OF OPERATIVE METHODS

The initial purpose of the present study was to cause muscular contracture of the leg in rabbits and thereby to produce foot deformities if possible. This notion had arisen from the quite common clinical observation that in foot deformities in man shortening of muscles and other soft tissue structures appear. The immediate impulse for these experiments was given by shortening of the *tibialis posterior* muscle and its transformation into a tight string which had often been noted in club foot operations (*Fried* 1959, *Langenskiöld* 1961). An attempt was therefore made to produce ischemic contracture by using various methods of blocking the blood circulation. It proved very difficult however to produce a permanent contracture in the leg muscles of a growing rabbit in accordance with earlier studies (*Brooks* 1922). An attempt was also made to produce contracture and fibrosis of the muscles both chemically (by the infiltration of carbolic acid for instance) and by means of electrocoagulation. No lasting contractures were obtained.

Younger and younger rabbits were taken as test animals as it was noticed that more reliable and lasting changes were produced in young rabbits than in older animals. Lasting changes in four week old rabbits rarely occurred. This is in agreement with the observations of *Crawford* (personal communication to *Hiley* 1959) when he immobilised the feet of a rabbit in dorsiflexion and caused increased resistance to full plantar flexion of the foot by means of resting tension. This myostatic contracture effect was less in adult rabbits than in young ones. For practical reasons the young of rabbits were usually 4-7 days old. Among still younger animals mortality was greater mainly because of abandonment by the mother.

E METHODS OF INVESTIGATION

1 Radiological study

The deformity and position of the bones were radiologically recorded in all animals. The first examination was made one week after operation. Radiographs were subsequently taken 3–4 weeks, 2 months, 3–4 months, 6 months and at least 1 year after operation. Further radiographs were taken even later if the animal remained alive. Finally, radiographs of the dissected specimens were taken. Dorsoplantar or anteroposterior and lateral projections of both limbs were used.

2 Cross section study

Almost all animals were dissected post mortem. Specimens were examined by inspection. Soft tissue changes, deformity and the position of bones were recorded and the degrees of deformity measured from radiographs. Photographs of specimens were taken when indicated.

3 Histological study

Specimens of eight animals were histologically examined. After fixation in neutral formalin and decalcification in ethylene diamine tetraacetic acid, the specimens were embedded in paraffin, sectioned in the desired planes and stained with haematoxylin and eosin.

were made near the ankle (ventral) and Achilles tendon (dorsal) Using normal tendon-stitching technique a nylon thread was sewn to the Achilles tendon The tendon was cut between the tendinous and muscular part drawn out and fixed through a hole bored in the middle of the tibia on the medial side so tightly that the talocrural joint was in extreme plantar flexion at the time of the operation On the ventral side transection of the muscles was performed, followed later as a rule by complete removal of part of the muscle and tendon to eliminate possible regeneration The same ventral incision enabled transection of the peroneal muscles and of the ligamentum transversum cruris to be performed

2 Plaster of Paris technique

Plaster immobilisation in fixed positions was performed by means of rapidly hardening Cellon[®] plaster bandage In order to avoid disturbance of blood circulation this was not applied to the whole circumference of the leg The plaster of Paris splint was tied loosely to the limb by gauze bandage As a rule the plaster remained firmly attached to the limb but because of the rabbit's fast growth it had to be changed once a week Like other procedures plaster was applied to the left hind limb leaving the right as a control

3 Fixation technique

With experimental animals on whom other methods of fixation than a plaster splint were applied in order to keep the foot in a fixed position the following technique was used By manipulation of the left hind limb the foot was brought into the desired position It was kept there by a nylon thread drawn through the foot between the metatarsals This thread was attached through the tibia halfway along the leg avoiding the principal nerves and blood vessels (Fig 3)

FIG 3 Diagrams to show examples of fixation of the foot of a growing rabbit in a calcaneovalgus position (left) and in a calcaneovarus position (right)

E METHODS OF INVESTIGATION

1 Radiological study

The deformity and position of the bones were radiologically recorded in all animals. The first examination was made one week after operation. Radiographs were subsequently taken 3-4 weeks, 2 months, 3-4 months, 6 months and at least 1 year after operation. Further radiographs were taken even later if the animal remained alive. Finally, radiographs of the dissected specimens were taken. Dorsoplantar or anteroposterior and lateral projections of both limbs were used.

2 Gross section study

Almost all animals were dissected post mortem. Specimens were examined by inspection. Soft tissue changes, deformity and the position of bones were recorded and the degrees of deformity measured from radiographs. Photographs of specimens were taken when indicated.

3 Histological study

Specimens of eight animals were histologically examined. After fixation in neutral formalin and decalcification in ethylene diaminetetraacetic acid, the specimens were embedded in paraffin, sectioned in the desired planes and stained with haematoxylin and Gierson.

were made near the ankle (ventral) and Achilles tendon (dorsal). Using normal tendon stitching technique a nylon thread was sewn to the Achilles tendon. The tendon was cut between the tendinous and muscular part, drawn out and fixed through a hole bored in the middle of the tibia on the medial side so tightly that the talocrural joint was in extreme plantar flexion at the time of the operation. On the ventral side transection of the muscles was performed followed later as a rule by complete removal of part of the muscle and tendon to eliminate possible regeneration. The same ventral incision enabled transection of the peroneal muscles and of the ligamentum transversum cruris to be performed.

2 Plaster of Paris technique

Plaster immobilisation in fixed positions was performed by means of rapidly hardening Cellon[®] plaster bandage. In order to avoid disturbance of blood circulation this was not applied to the whole circumference of the leg. The plaster of Paris splint was tied loosely to the limb by gauze bandage. As a rule the plaster remained firmly attached to the limb but because of the rabbit's fast growth it had to be changed once a week. Like other procedures plaster was applied to the left hind limb leaving the right as a control.

3 Fixation technique

With experimental animals on whom other methods of fixation than a plaster splint were applied in order to keep the foot in a fixed position the following technique was used. By manipulation of the left hind limb the foot was brought into the desired position. It was kept there by a nylon thread drawn through the foot between the metatarsals. This thread was attached through the tibia halfway along the leg avoiding the principal nerves and blood vessels (Fig. 3).

FIG. 3. Diagrams to show examples of fixation of the foot of a growing rabbit in a calcaneovalgus position (left) and in a calcaneovarus position (right).

F METHODS OF INVESTIGATION

1 Radiological study

The deformity and position of the bones were radiologically recorded in all animals. The first examination was made one week after operation. Radiographs were subsequently taken 3-4 weeks, 2 months, 3-4 months, 6 months and at least 1 year after operation. Further radiographs were taken even later if the animal remained alive. Finally, radiographs of the dissected specimens were taken. Dorsoplantar or antero-posterior and lateral projections of both limbs were used.

2 Gross section study

Almost all animals were dissected post mortem. Specimens were examined by inspection. Soft tissue changes, deformity and the position of bones were recorded and the degrees of deformity measured from radiographs. Photographs of specimens were taken when indicated.

3 Histological study

Specimens of eight animals were histologically examined. After fixation in neutral formalin and decalcification in ethylene diamine-tetra-acetic acid, the specimens were embedded in paraffin, sectioned in the desired planes and stained with haematoxylin and *van Gieson*.

Γ OPERATIONS PERFORMED

The operations were confined to the leg region as far as possible since operations performed on the foot itself would make estimation of peripheral changes impossible (Fig 15, p 48). Operations on the leg muscles and tendons together with the ligamentum transversum cruris offer an infinite number of possible combinations though not all combinations are adequate for the production of specific effects of muscle imbalance. Nineteen different measures were used besides four fixation methods (Table 1).

Table 1 Operative and plaster immobilisation measures with abbreviations taken in experiments with soft tissue components

A_1	= Achilles tendon fixation (tenodesis)
A_T	= Achilles tendon transection or resection
E_1	= extensor digitorum longus muscle or tendon fixation
A_s	= Achilles tendon shortening
$A \rightarrow TA$	= Achillo tibial tenoplasty
$A \rightarrow (E+TA)$	= Achillo extensoro tibial tenoplasty
E_T	= extensor digitorum longus muscle or tendon transection
TA_T	= tibialis anterior muscle or tendon fixation
TA_T	= tibialis anterior muscle or tendon transection
P_T	= transection of all peroneal muscles or tendons
PB_T	= peroneus brevis tertius and quartus muscles or tendons transection
PI_T	= peroneus longus muscle or tendon transection
TP_F	= tibialis posterior muscle (extensor digiti primi) or tendon fixation
TP_T	= tibialis posterior muscle (extensor digiti primi) or tendon transection
F_1	= flexor digitorum longus muscle or tendon fixation
F_T	= flexor digitorum longus muscle or tendon transection
L_T	= transection of ligamentum transversum cruris
K_E	= plaster of Paris immobilisation in equinus position
K_V	= plaster of Paris immobilisation in varus position

Possibilities of combinations of these measures were too great in number for a completely systematic study. It was therefore necessary to start from certain hypotheses and continue the choice of combinations on the basis of results in order to achieve specific deformities. The next aim was to make a selective search for significant factors in the cases of experimental deformity produced by analysing the dissected specimens. The simplest possible combinations for the production of deformity were thus determined. Negative results were also important in explaining the factors leading to deformity.

A total of 76 operations or other measures including plaster or other fixation were performed (Table 2).

IV RESULTS

A TALIPES EQUINOVARUS

1 General description of deformity produced and factors leading to deformity

When the records of the experiments were reviewed it was found that there was a clear regularity in the procedures leading to talipes equinovarus deformity (Table 3) Achilles tenodesis was always performed producing an equinus position of the calcaneus if it had not been already produced by plaster immobilisation or other fixation. In most rabbits with equinovarus deformity transection of both the extensor digitorum longus muscle and the peroneus muscles had been performed (Table 3)

Table 3 Structural talipes equinovarus deformity in rabbits resulting from various procedures

Transection of the ligamentum transversum cruris was also performed on several animals developing equinovarus deformity but the deformity also appeared without this measure. Severing the ligament clearly accentuated the deforming effect of the tibialis anterior and augmented the adducto-varus position of the metatarsus. In some rabbits where the equinovarus position appeared in other combinations careful dissection explained the factors which led to the changes. Here too soft tissue changes were in accordance with the deformity and explained its development. Thus in Series XIII no 5 in which the combination Achilles tenodesis and transections of the tibialis anterior and peroneal muscles had produced equinovarus it was noted that the extensors were atrophied

while the tibialis anterior had become reattached. Muscle-tendon resections had not yet been performed. When the test series were renewed using resections this combination did not lead to the equinovarus deformity. Similarly in Series XXIV no 3 ($A_T + E_T + TA_T + TP_T$) and Series XXVI no 5 ($A_T + E_T + TA_T + TP_T$) in which muscle tendon resections had not yet been performed but dissections had been extended to include the tibialis anterior and the tibialis posterior it appeared at macroscopic examination that re adhesion and contracture had occurred in the region of the tibial muscles. In Series XXVIII no 1 where in addition to the combination Achilles tenodesis and transections of the extensor digitorum and peroneal muscles severing of the flexor digitorum had been performed dissection revealed that the flexors had become attached and were tight. In Series LVII no 7 with Achilles tenodesis and transection of the ligamentum transversum cruris atrophy of the extensor and peroneal muscles was noted as a possible result of a lesion of the peroneal nerve arising accidentally with Achilles tenodesis.

In other animals an equinovarus deformity developed either through external fixation with nylon thread in the equinovarus position (Series XII no 7) or through fixation in the equinovarus position by means of plaster (Series LVIII no 1 etc). But immobilisation must be continued sufficiently long time three weeks at the least. Then a permanent even progressive deformity developed.

Two interesting experiments are in Series LV nos 1 and 4. Transections of the extensor digitorum and peroneal muscles were performed in connection with immobilisation by plaster in the equinus position producing a typical equinovarus deformity.

On the other hand no deformity with equinovarus position developed when resections of the Achilles tendon the tibialis anterior and tibialis posterior muscles were made in connection with plaster immobilisation in the equinovarus position. Nor was equinovarus deformity produced in series where one of the factors Achilles tenodesis transections of the extensor digitorum or peroneal muscles was omitted from the combination.

Talipes equinovarus deformity was produced in the following combination of three components summarized as follows:

First the proximal part of the Achilles tendon was drawn through a hole bored in the middle part of the tibial diaphysis and fixed to the bone. Tenodesis was thus performed.

Second transection of the peroneal muscles and the extensor digitorum longus muscle was performed. A pronal effect was thus eliminated.

Third the tibialis anterior the tibialis posterior and flexor digitorum longus muscles with their supinatory effects were left intact.

FIG 4 X ray pictures in the dorsoplantar projection of talipes equinovarus of a child (left) and of experimental talipes equinovarus in a rabbit Series XXXIII no 1 (right)

General skeletal structure and relative positions of tarsal bones are strikingly similar

2 Comparison of experimental talipes equinovarus in the rabbit and talipes equinovarus in man

a) General comparison

The deformity known as talipes equinovarus or club foot comprises the following components: adduction of the fore foot, varus or inversion of the heel and equinus of the entire foot (Hise 1964). Club foot also has a cavus deformity (Ponseti and Smoley 1963).

In all experimental foot deformities noted in Table 3 it was possible to show these different components (Figs 4 and 12).

Clinical examination of the pathology of talipes equinovarus in man is an easy matter since the bones of the foot can be clearly palpated. In a club foot the talus is in approximately the same position as in a normal foot but it has been strongly adducted and plantar flexed. The fore foot and os calcis are medially rotated and displaced around the talus. The lateral malleolus is prominent but the medial malleolus is difficult to find by touch. Also the head of the talus is prominent on the lateral side of the dorsum pedis. The calcaneus is in inversion and equinus deformity.

In rabbits with equinovarus deformity the same general changes could be found (Figs 5 and 7)

A ray examination clarifies the position of the bones in the foot and their relationship to one another. Comparison of the radiographic appearance of the experimental equinovarus deformity in rabbits with equinovarus deformity in children revealed striking similarities. In the dorsoplantar projection it can be seen that the calcaneus has turned into the inversion position under the talus. The fore-foot is adducted. The navicular, cuboid, cuneiforms and metatarsals are displaced medially and the fore foot is thus in adduction deformity. The navicular is medial to the head of the talus and the cuboid medial to the distal end of the calcaneus (Fig. 4).

b) Patho-anatomical comparison of position of bones in relation to each other

The patho anatomical changes in the bones of club-feet were already noted at the end of the 18th century (Blumenbach 1786, Clossius 1798, Hanck 1798 etc. according to Krenn 1927). Antonio Scarpa in 1803 thought that the deformity was caused by the navicular, cuboid and calcaneus moving medial to the talus. He observed this while examining club feet in children. Renewed study has led to the conclusion that the most notable divergence from normal in the relation of the bones of a club foot apart from the plantar flexed position of the talus is the more medial position of the navicular in relation to the head of the talus (Krenn 1927, Virchow 1933, Wiley 1959, Irani and Sherman 1963, Ponseti and Smoley 1963). Debrunner in his monograph suggests that the structure of a club foot is understandable as a twisting of the calcaneus, the cuboid, the navicular and the whole fore foot into inversion and adduction around the talus. Brockman (1930) noted that in a club foot there is subluxation of the talocalcaneonavicular joint and alterations in the position of the navicular and calcaneus in relation to the talus. The talus is also in the equinus position in the tibio-fibular mortise and it has even been said that a forward subluxation of the talus is present (Marique 1946).

When comparing the position of the bones of experimentally produced equinovarus feet with that in a normal foot, the changes observed have been very similar to those noted in the literature concerning club foot in man (Figs 6 and 8).

FIG 5 Gross anatomical structure of the bones in rabbit talipes equinovarus Series XXVIII no 3 front view

FIG 6 Diagram of Fig 5 compared with diagram of corresponding human talipes equinovarus according to *Arlet* (1927) (By courtesy of Arch orthop Unfall Chir)

In both the foot is displaced and rotated medially below the talus. The head of the talus is on the lateral side of the dorsum of the foot owing to the medial and plantarward displacement of the navicular.

FIG. 8 Diagram of Fig 7 compared with diagram of corresponding human talipes equinovarus according to Heyutz (197) (By courtesy of Arch orthop (Infall Clin))

In both the calcaneus is in a severe equinus position with its anterior portion lying below the head of the talus. The cuboid is also displaced inward.

FIG 9 Roentgenogram in the dorsoplantar projection of a rabbit talipes equinovarus Series XXXII no 7

c) Radiological comparison of the talo calcaneal angle

X-ray studies add much information about talipes equinovarus to that obtained from clinical examination

The essential difference between a club foot and a normal foot in man is the difference in the angle formed by the longitudinal axes of the talus and the calcaneus. According to *Debrunner* (1957) the difference in this angle is so great that a diagnosis can be made on the basis of the roentgenogram alone. Small changes in the talo calcaneal angle can be seen on a lateral X ray but the most significant pathology is best seen in the dorsoplantar projection. In the normal human foot the talo calcaneal angle in the dorsoplantar projection is a distally open angle of 30—45 degrees according to *Debrunner* and 35—40 degrees according to *Thomassen* (1941). In a club foot the calcaneus is under the talus and the angle between their longitudinal axes the talo-calca-neal angle decreases with the degree of severity. Thus in an extreme

FIG 10 Top diagrams of the dorsoplantar roentgenograms of rabbit's normal foot and club foot Series XXXII no 7 Bottom corresponding diagrams of human feet (Davis and Hatt 1955) (By courtesy of Radiology)

Both in rabbit club foot and human club foot the same radiological changes can be found the talo-calcaneal angle approaches 0° or is reversed the mid talar line lies lateral to the normal position the mid calcaneal line lies medial to the normal position the mid talar line and the line through the shaft of the first metatarsal form an angle

case the axes are parallel or the angle between them may even be reversed (Davis and Hall 1955)

It was possible to measure a similar change of angle between the longitudinal axes of the talus and the calcaneus in the dorsoplantar projection in all experimental talipes equinovarus feet (Figs 9 and 10)

d) Comparison of changes in the shape of the talus and the joint surfaces

Descriptions in the literature of bony abnormalities of dissected infantile club-feet in humans are in close agreement with each other. They suggest that among the changes in the shape of separate bones the most important is the change in the shape of the talus. Adams (1851-1852) found the greatest changes in the neck and head of the talus. The same was noted in later dissection studies (Kocher 1878, Parker and Shallock 1884, Bissell 1888, Bessel-Hagen 1889, Burrell 1893, Nichols 1897, Sheikunenko 1899, Bohm 1929) and described in many other publications (Mau 1927, Kreuz 1927, Trues 1931, Virchow 1933, Debrunner 1936). Iranz and Sherman in 1963 dissected eleven extremities with equinovarus deformity recovered from stillbirths or from neonatal deaths and constantly found abnormality in the anterior part of the talus. In his publication of 1963, Settle presented the earlier literature on dissections of infantile congenital talipes equinovarus collected by him. He also described his anatomical findings in sixteen dissected infantile club feet. In the literature dealing with 52 club feet he noted in 44 cases the same deformity: severe distortions of the head and neck as in his own cases. Reimann (1967) dissected six fetuses stillborn and children with club feet who had died and found almost constantly skeletal changes affecting the talus.

The main deformity in the bones of club feet in fetuses was in the neck of the talus which was markedly deviated medially and plantarwards on

FIG 11 Top the talus of a normal foot (R_p) and of a talipes equinovarus foot (R_v) of the same rabbit. Series XXXII no 6 seen from the calcaneal side.

Diagrams of these photographs compared with corresponding diagrams of the tali of human normal foot (H_n) and club foot (H_v) from the late fetal period according to Settle (1963) (By courtesy of J Bone Jt Surg.)

Similarities between the normal talus and the talus of club foot in both human and rabbit are marked: the tali of club feet have an obvious medial rotation of the neck, the articular surface towards the navicular is displaced medially and plantarward in club feet, the anterior articular surface towards the calcaneus is missing.

d) Comparison of changes in the shape of the talus and the joint surfaces

Descriptions in the literature of bony abnormalities of dissected infantile club feet in humans are in close agreement with each other. They suggest that among the changes in the shape of separate bones the most important is the change in the shape of the talus. Adams (1851—1852) found the greatest changes in the neck and head of the talus. The same was noted in later dissection studies (Kocher 1878, Parker and Shattock 1884, Bissell 1888, Bessel Hagen 1889, Burrell 1893, Nichols 1897, Sheikunenko 1899, Bohm 1929) and described in many other publications (Mau 1927, Krenz 1927, Treves 1931, Virchow 1933, Debrunner 1936). Iram and Sherman in 1963 dissected eleven extremities with equinovarus deformity recovered from stillbirths or from neonatal deaths and constantly found abnormality in the anterior part of the talus. In his publication of 1963, Settle presented the earlier literature on dissections of infantile congenital talipes equinovarus collected by him. He also described his anatomical findings in sixteen dissected infantile club feet. In the literature dealing with 52 club feet he noted in 44 cases the same deformity: severe distortions of the head and neck, as in his own cases. Reimann (1967) dissected six fetuses, stillborns and children with club feet who had died and found almost constantly skeletal changes affecting the talus.

The main deformity in the bones of club feet in fetuses was in the neck of the talus which was markedly deviated medially and plantarwards on

Diagrams of these photographs compared with corresponding diagrams of the tali of human normal foot (H_n) and club foot (H_e) from the late fetal period according to Settle (1963) (By courtesy of J Bone Jt Sur.)

Similarities between the normal talus and the talus of club foot in both human and rabbit are marked: the tali of club feet have an obvious medial rotation of the neck, the articular surface towards the navicular is displaced medially and plantarward in club feet, the anterior articular surface towards the calcaneus is missing.

Fig 11

FIG 1 Top the medial side of the tali of a rabbit left from a club footed specimen (R_f) right from a normal one (R_n) Series XXXII no 6

The centre pictures are diagrams of these tali

The bottom illustrations are corresponding diagrams of tali in human congenital equinovarus foot (H_f) and in human normal foot (H_n) (Sell 1963) (By courtesy of J Bone Jt Surg.)

In this direction the similarities between the normal talus and the talus of club foot in both human and rabbit are all so obvious both tali of human and rabbit club foot have the same kind of plantar deviation of the neck and medial displacement of the articular surface towards the navicular

the body of the talus The angle between the long axis of the neck and the long axis of the body of the normal talus is 150–155 degrees while in a club foot it is 115–135 degrees (Irani and Sherman 1963) Upon the deformed and deviated neck of the talus the talonavicular articular surface displaces still further medially and plantarwards increasing the deformity even more The subtalar articular surfaces fuse together in a

single distorted articular surface which faces medially in internal rotation and equinus (*Settle 1963*)

The same pathological changes as in the talus of an infantile club foot have also been noted in these macro-anatomical studies of experimental club foot in rabbits. The degree of deformity in the talus was directly proportional to the degree of equinovarus deformity. The more extreme the equinovarus position the greater the medial deviation of the neck of the talus and the medial displacement of the talonavicular articular surface (Figs 11 and 12)

The navicular in experimental equinovarus feet is regularly smaller than in a normal foot in the same rabbit. This has also been noted in fetal club feet (*Irans and Sherman 1963 Settle 1963*)

Changes in the shape of other bones and articular surfaces of club-feet in both humans and rabbits are smaller. The calcaneus and cuboid remain almost normal as the literature has suggested (*Irans and Sherman 1963 Settle 1963*). In extreme experimental equinovarus feet however these bones show greater changes corresponding to the deformity.

e) Comparison of changes in soft tissues

There are very few good anatomical studies on soft tissue changes in club-foot deformity. Clinical observations and those made during operations on club-feet are numerous but they are partial and separate observations and do not cover all the factors having an effect in these cases. Earlier authors mainly clarified the bone changes and not until recent decades have soft tissue changes received the attention they deserve. However *Little (1839)* had already shown that uncoordinated muscle function or abnormal tendon insertions could cause club foot deformity. Most investigators have studied tendon insertions and found anomalies in them (*Scherb 1930 Penners 1954 Debrunner (1957)*) wrote that these anomalies have been found in almost all the tendons of club feet.

A general observation in talipes equinovarus specimens in rabbits produced both by means of Achilles tenodesis and by plaster and fixation immobilisation was the displacement of the Achilles tendon insertion to the medial side of the tuber calcanei. On the other hand the calcaneus in relation to the talus rotates into inversion and thus it is difficult to say whether it is a displacement of the tendon insertion or a displacement of the bone in relation to the tendon. A similar Achilles tendon displacement has however been observed in many examinations

FIG 1. Top the medial side of the tali of a rabbit left from a club footed specimen (R_t) right from a normal one (R_n) Series XXXII no 6

HUMAN

Fig 13

of club foot in man (*Flinchum 1953 Penners 1954 Inclan 1958*) In his studies *Stuart* (1951) frequently found this tendon insertion anomaly which strengthens the supinating effect of the Achilles tendon

When analyzing the gross talipes equinovarus specimens in rabbits it was always noticeable that supinating muscle tendon structures the Achilles tendon the tibialis anterior and tibialis posterior muscles and the flexor digitorum muscles were shortened and taut compared with the normal foot of the same rabbit These changes occurred in experimental deformities produced by Achilles tenodesis and by transection of the peroneal muscles and the flexor digitorum longus muscles or in club foot deformities produced by immobilisation into the equinovarus position In club foot in man the Achilles tendon contracture is a constant phenomenon From his investigations *Stewart* draws the conclusion that the triceps surae muscle the tibialis anterior muscle and the short plantar muscles are positively deforming forces while the peroneal muscles are insufficient and do not prevent the foot from turning to wards equinovarus deformity Other authors have also placed emphasis on either the contracture or fibrosis and shortening of the tibialis posterior muscle (*Mau 1930 Fried 1959*) or the abnormal resistance to eversion of the tibialis anterior muscle (*Flinchum 1953*) Recently *Attenborough* (1966) has confirmed the finding of small muscle bellies and shortness of the gastrocnemius soleus tibialis posterior and flexor digitorum longus muscles in stillborn infants with club feet

In the experimental talipes equinovarus specimens it has been possible to observe similar shortening and contractural tightening of the Achilles tendon the tibialis anterior and posterior muscles and the flexor digitorum longus muscles as described in the literature (Fig 13)

FIG 13 Top left a picture of a rabbit club foot Series LVIII no 7 top right a diagram of the same picture

1) Micro anatomical comparison

Bernbeck (1954) has presented micro-anatomical studies on talipes equinovarus specimens of fetuses in which a marked bone deformity was clearly seen. The greatest change was in the talonavicular joint where the navicular had shifted medially and plantarward around the talus. The fore-foot and cuboid also shifted with the navicular.

In all three micro anatomical studies of vertical sections of experimental talipes equinovarus deformities in rabbits a similar striking bone change could be found (Fig. 14).

In these experiments on rabbits as well as in *Bernbeck's* studies molding of the head of the talus and the navicular can also be seen. The neck of the talus has deviated medially, the navicular articulation with the talus has an inclination towards the medial surface of the foot and the talonavicular and the calcaneocuboid joints have turned medially.

Macroscopic analysis of the vertical talus specimens thus obtained led to the conclusion that sufficiently tight fixation of the Achilles tendon to the tibia causes the calcaneus to turn downwards in plantar flexion. At the same time it is clear that the talus also turns more vertically.

Severing of the *ligamentum transversum cruris* causes the *tibialis anterior* and *extensor digitorum longus* muscles to become insufficient at first but later they shorten and begin to tighten (Fig 15 p 48). In addition *the tendons of the extensor digitorum longus adhere to the dorsum pedis and the muscle effect is transferred from the toes to the tarsus*. Similarly the pull of the *tibialis anterior* muscle is exerted more directly towards the insertion point at the base of the first metatarsal. In operations on several children with vertical talus deformity at the Orthopaedic Hospital of the Invalid Foundation it was noted that the tendons of the *extensor digitorum longus* in these cases adhered to the *dorsum pedis* in the same way (Langenskiöld 1964) thus causing a transference of muscular pulling effect from the toes to the forepart of the tarsus as in the rabbits with the experimentally produced deformity.

Vertical talus deformity also developed when either the *extensor digitorum longus* or the *tibialis anterior* muscles were resected in addition to sectioning of the *ligamentum transversum cruris* and fixation of the Achilles tendon. The two forms of vertical talus thus obtained differ from each other. If the *tibialis anterior* is resected a deformity arises with dorsal flexion, pronation and abduction in the distal part of the foot (Fig 20 p 55) the changes occurring mainly at the mid tarsal joint. If in turn the *extensor digitorum longus* muscles are resected a slight supination towards dorsiflexion in the distal part of the foot and a tendency to varus position are provoked (Fig 18 p 54). Vertical talus deformity produced merely by discision of the *ligamentum transversum cruris* and fixation of the Achilles tendon are predominantly of the first type: the *extensor digitorum longus* and the peroneal muscles strength overcoming the effect of the *tibialis anterior*. When the children with vertical talus deformity seen at the Orthopaedic Hospital of the Invalid Foundation were examined it was possible to distinguish both these vertical talus deformity types (Langenskiöld 1964).

In the so-called *tibialis anterior* type (Figs 17 and 18 p 54) the *tibialis anterior* tendon is a tightened and shortened element on the anterior side of the ankle while in the so-called *extensor digitorum* type (Figs 19 and 20 p 55) the *extensor tendons* and the *peroneal tendons* are contracturally tightened and shortened.

It is a fact of great interest that when tension of the Achilles tendon which is produced by evident myostatic contracture of the gastrocnemius and soleus muscles secondary to plaster immobilisation alone was combined with a myostatic dorsiflexion contracture produced by transection of the ligamentum transversum cruris a vertical talus deformity also developed (Fig 16)

FIG 16 Vertical talus deformity in a rabbit Series L&I no 3 produced by plaster immobilisation and transection of the ligamentum transversum cruris The sole is convex the calcaneus is in the equinus position the fore foot is in dorsiflexion and the talus is in a clearly vertical position

2 Comparison of experimental vertical talus in the rabbit with vertical talus in man

a) General comparison

Though the clinical picture should cause suspicion of the vertical talus deformity it is the radiograph which is characteristic. Therefore the general comparison of both the tibialis anterior and the extensor digitorum types in children and rabbits is presented by means of X ray pictures.

In the lateral projection in both types in rabbits and in man the sole is convex the forepart of the foot is in dorsiflexion and the talus points downwards into the sole of the foot. The calcaneus is carried into the equinus position with the talus. The navicular does not articulate with the head of the talus but faces the dorsal surface of its neck (Figs 17 and 19).

In the anteroposterior projection the tibialis anterior type has a slight supination of the forepart of the foot while the extensor digitorum type has clear pronation (Figs 18 and 20).

There are remarkable similarities in the general shape of the bones and the relative positions of separate bones in children and in rabbits.

b) Patho-anatomical comparison of the position of bones in relation to each other

There are few investigations dealing with the gross anatomical changes in the vertical talus deformity. Usually only the clinical and radiological characteristics of the deformity have been described. The only detailed description from earlier times is according to *Guntz* (1939) that of *Kustner* (1880). It was not until 1939 that *Guntz* carefully examined the pathology of the congenital flat-foot deformity by dissecting the deformed feet of a stillborn child. He found the same bone changes as *Kustner*. In 1963 *Herndon* and *Heyman* presented illustrations of the pathological anatomy of the congenital convex pes valgus as they term the congenital vertical talus. A complete patho-anatomical study of a six week old infant with bilateral congenital convex pes valgus has been published very recently (*Patterson Fitz and Smith* 1968).

According to earlier examinations, the downward rotation of the talus into a vertical position and subluxation of the navicular which articulates with the dorsal aspect of the neck of the talus locking it in a plantar flexed position are essentials in the bone relationships of congenital flat-foot or congenital convex pes valgus deformity.

In all rabbits with vertical talus it was exactly this relationship of the talus and the navicular that was very obvious. It was very difficult during dissection to separate the talus and to turn it from the vertical position without breaking the bones because the talus was locked in a plantar flexed position by the navicular (Fig 21).

From the dorsal aspect it was essential that the head of the talus was directed medially and inferiorly with the result that the axis of the talus deviated more medially than normally (Figs 22 and 23).

FIG. 2. Patho anatomical pictures of the dorsal aspect of vertical talus deformity (left) and (right) normal foot in a rabbit. Series XL no. 2. Tibia has been removed. In vertical talus deformity the long axis of the talus deviates medially and the neck has been turned medially and plantarward.

The diagrams show an increased talo-calcaneal angle in the deformed feet on the lateral projection both in man and rabbit

c) Radiological comparison of the talo-calcaneal angle

In order to estimate and compare the X ray examinations of the foot objectively, it is necessary to draw axes of the bones and to measure the angles formed by them. Changes in the angle formed by the longitudinal axes of the talus and the calcaneus (the talo calcaneal angle) are characteristic of the congenital vertical talus and also of the congenital club foot. *Guntz* (1939) has made a thorough radiological comparison of various foot deformities. He has found that the talo calcaneal angle both in lateral and dorsoplantar projections in all flat foot deformities is wider than normal. *Huner* (according to *Niederecker* 1959) has measured the talo calcaneal angle in the lateral projection of the normal foot at a minimum of 20 degrees while it can be 90 degrees in congenital flat-foot. *Siegmund* reported (according to *Hohmann* 1951) the talo calcaneal angle in the lateral projection to be 50–90 degrees in congenital flat foot and 28 degrees in normals.

Radiographs taken in the dorsoplantar projection reveal medial displacement of the distal part of the talus. This radiographic finding is similarly described by *Osmond Clarke* (1956), *Lloyd Roberts* and *Spence* (1958), *Haverson* (1959), *Ouland* and *Sherk* (1960), *Herndon* and *Heyman* (1963). Apart from *Cuntz*, other German authors have also observed the increase in the talo calcaneal angle in the dorsoplantar projection. According to *Hohmann*, the talus in congenital flat-foot can be directed transversally to the calcaneus which is in the direction of the longitudinal axis of the foot. In clinical material *Huner* has found the talo calcaneal angle in the dorsoplantar projection to be about 20 degrees in normals but much wider in congenital flat foot up to 45 degrees. On the other hand *Støren* (1967) claims that the talo-calcaneal angle is reduced in the dorsoplantar projection in congenital convex pes valgus with vertical talus but not in all cases.

In rabbits with vertical talus, an increase in the talo calcaneal angle both in the lateral and the dorsoplantar projection in comparison with the normal foot could be found (Figs 24, 25 and 26).

e) Comparison of changes in soft tissues

In order to clarify possible deforming factors in experimentally produced vertical talus deformity muscle and tendon structures were examined macroscopically. It was found that the equinus position of the hindpart of the foot and the Achilles tendon contracture or shortening could be developed either by Achilles tenodesis or by plaster or external fixation of the os calcis in the equinus position.

Many earlier investigators have observed the Achilles tendon shortening or contracture in vertical talus deformity in children (Hareson 1959 Herndon and Heyman 1963 Patterson Fil. and Smith 1968). Many authors have also suggested an elongation of the tightened Achilles tendon in operative reduction of the congenital vertical talus deformity (Rocher and Pouyanne 1934 Hark 1950 Hohmann 1951 Outland and Sherk 1960 Mead and Anast 1961).

According to Gunt's patho-anatomical examination of the vertical talus deformity the Achilles tension did not seem to be noticeable in the deformed position but when the lateral dislocation of the calcaneus was reduced to the normal position the Achilles tendon had to be tenotomized because the lateral fibres tightened and thus prevented reduction.

In one group of rabbits with experimental vertical talus deformity tension of extensor and peroneal tendons caused a dorsiflexion position of the fore foot. This was called the extensor digitorum type. In most cases described in the literature the dorsiflexion contracture has been observed in precisely the extensor digitorum longus and peroneal tendons (Mead and Anast 1961 Herndon and Heyman 1963) and many authors found that a transection of the tibialis anterior tendon was not indicated or proved useful if performed (Osmond Clarke 1956 Lloyd Roberts and Spence 1958 Herndon and Heyman 1963).

In another group of rabbits with vertical talus deformity tibialis anterior and extensor digitorum longus tendon tension could be found. The literature also contains reports of similar contractures in the vertical talus deformity in man (Hark 1950 Outland and Sherk 1960 Patterson Fil. and Smith 1968).

In the third group of rabbits with vertical talus deformity the essential dorsiflexion contracture was found in the tibialis anterior tendon. This group was called the tibialis anterior type. Hughes (1957) has stated that in the congenital vertical talus in man there are also contractures of the anterior soft parts particularly the tibialis anterior muscle. However German writers in particular have put emphasis on

the tibialis anterior contracture as a deforming factor in der angeborene Knickplattfuß as they term the congenital vertical talus Guntz (1939) made an exact patho anatomical study of the congenital flat foot and found the tibialis anterior tendon a factor that hindered the plantar flexion of the fore foot. It tightened like a string from the leg to the dorsum of the foot at the same time as the ligamentum cruciatum cruris had moved more proximally fusing with the ligamentum transversum cruris (Fig 29). According to Guntz the extensor digitorum longus tendons also tighten strongly in the plantarflexion position of the fore foot. On the basis of extensive material consisting of operated flat feet Niederecker (1950) emphasized that functional factors or muscle anomalies are more important than bone factors. He considered that the hypertrophy and contracture of the tibialis anterior muscle strengthened the development of the flat foot deformity. He also noted that the insertion of the tibialis anterior tendon very significant in flat foot deformity had moved forwards to the first metatarsal bone. Patterson Fitz and Smith (1968) described also the bowstringing of the anterior tibial tendon (Fig 29).

In rabbits in which the peroneal muscles were preserved contractural shortening could be observed especially in the extensor digitorum type. Guntz (1939) has referred to the contracture of the peroneus brevis muscle and its deforming effect in man. Herndon and Heyman (1963) have also noticed the contracture of both peroneal muscles. During the operative reduction of the congenital vertical talus feet of children at the Orthopaedic Hospital of the Invalid Foundation the peroneus tertius muscle and its contracture and deforming effect have often been found (Langenskiöld 1964). Niederecker (1950) has also observed the occurrence and the importance of this muscle in flat foot deformity.

But even if the muscle and tendon contractures in vertical talus experiments were released it was not possible to correct the deformity and the position of the talus until the ligamentous contractures were released. In rabbits it was found that the most important factors that hindered the correction of the vertical talus deformity were the talo navicular ligament the tibiocalcaneal intercrosseum ligament and especially the tibionavicular ligament. Many authors have paid attention to the significance of these ligamentous factors in the congenital vertical talus deformity during the operative reduction of this deformity (Harl 1950, Osmond Clarke 1956, Mead and Inast 1961, Herndon and Heyman 1963, Støren 1967).

V DISCUSSION AND CONCLUSIONS

The purpose of the studies described above was not to determine the unexplained primary etiology of congenital deformities of the foot but to analyse the part played by muscle imbalance and by soft tissue factors especially in the pathogenesis of structural bone deformities of the foot. The aim was also to produce in the growing rabbit by measures performed on soft tissues and through muscle imbalance and contracture experimental changes which resemble foot deformities seen in humans.

Therefore only the muscle and other soft tissue contractures related to human foot deformities and to animal experiments are discussed. In addition only the points in common which could be noted when comparing the morphological, radiological, patho-anatomical and especially soft tissue changes of talipes equinovarus and vertical talus produced in rabbits with these deformities in man are discussed. Conclusions have been made on the same bases.

A MUSCLE IMBALANCE AND SOFT TISSUE CONTRACTURES RELATED TO CONGENITAL FOOT DEFORMITIES IN MAN AND TO ANIMAL EXPERIMENTS

In connection with paralytic deformities which include both traumatic deformities and those following poliomyelitis many observations were made of bone changes arising from changes in the soft tissues. In poliomyelitis for instance where imbalance of muscle power is the cause of deformity restoration of muscle imbalance when effected sufficiently early by appropriate transposition of tendons has often prevented the development of a seriously progressive deformity such as talipes calcaneus or varus and especially its transformation into a structural bone deformity. In addition much information on patho-anatomical soft tissue changes in congenital deformities especially club-foot has been obtained. The old static conception of bone deformity as a primary condition is yielding to more dynamic thinking although studies still appear which place bone deformity in the foreground (Thomassen 1941 Doyle

f) Micro anatomical comparison

Five vertical talus specimens of rabbits were sectioned and examined histologically in the sagittal plane through the talo-navicular joint

The following similar phenomena in the sagittal plane of both the vertical talus experiments in rabbits and the vertical talus deformity in an infant can be seen in the illustrations (Fig 30) The navicular has an abnormal articulation with the superior surface of the neck of the talus, the talus rotates toward the plantar surface into a vertical position and the deformed appearance of the head of the talus is demonstrated here as in Fig 28

V DISCUSSION AND CONCLUSIONS

The purpose of the studies described above was not to determine the unexplained primary etiology of congenital deformities of the foot but to analyse the part played by muscle imbalance and by soft tissue factors generally in the pathogenesis of structural bone deformities of the foot. The aim was also to produce in the growing rabbit by measures performed on soft tissues and through muscle imbalance and contracture experimental changes which resemble foot deformities seen in humans.

Therefore only the muscle and other soft tissue contractures related to human foot deformities and to animal experiments are discussed. In addition only the points in common which could be noted when comparing the morphological, radiological, patho-anatomical and especially soft tissue changes of talipes equinovarus and vertical talus produced in rabbits with these deformities in man are discussed. Conclusions have been made on the same bases.

A MUSCLE IMBALANCE AND SOFT TISSUE CONTRACTURES RELATED TO CONGENITAL FOOT DEFORMITIES IN MAN AND TO ANIMAL EXPERIMENTS

In connection with paralytic deformities which include both traumatic deformities and those following poliomyelitis many observations were made of bone changes arising from changes in the soft tissues. In poliomyelitis for instance where imbalance of muscle power is the cause of deformity restoration of muscle imbalance when effected sufficiently early by appropriate transposition of tendons has often prevented the development of a seriously progressive deformity such as talipes calcaneus or varus and especially its transformation into a structural bone deformity. In addition much information on patho-anatomical soft tissue changes in congenital deformities especially club foot has been obtained. The old static conception of bone deformity as a primary condition is yielding to more dynamic thinking although studies still appear which place bone deformity in the foreground (*Thomassen 1941 Doyle*

1961 *Iram and Sherman 1963*) An increasing number of recent investigators have directed their attention to soft tissue anomalies in congenital and idiopathic deformities (*Scherb 1930 Stewart 1951 Fincham 1953 Langenskiöld and Michelsson 1961 Debrunner 1957*) for instance has suggested that an essential feature of club foot is active contracture of the soft tissues caused by disturbed muscle balance

Close investigation of bone changes in various congenital foot deformities has led to greater uniformity, but observations on soft tissue changes vary. Although contractural changes in them are often observed the microscopic findings themselves are variable. This is in agreement with the statement of *Ierguson, Vaughan and Ward (1957)* that histological changes in muscle are notoriously difficult to evaluate and disagreement is to the presence or absence of histological changes runs throughout the literature on disuse atrophy and myostatic contracture. The only difference microscopically between the muscles in club foot deformity and those of a normal foot is that in the former atrophied muscle fibres are found between normal ones (*Man 1930*) or the average diameter of the muscle fibres is diminished (*Reimann 1967*). This is most noticeable in supinatory muscles. But a similar discovery has been made in polio myelitis that is in muscles which have changed through disturbance of the central nervous system and also in ischemic contractural muscles (*Debrunner 1957*). Thus *Debrunner* has said that congenital club foot is the brother of paralytic club foot.

As soft tissue contracture is a conspicuous feature of congenital foot deformity at least in its later stages the attempt to produce muscle contracture in the leg of a growing rabbit and thus possibly to imitate congenital foot deformities was of interest. Ischemic contracture seemed suitable for this purpose but permanent contracture was not obtained by this means. Why was ischemic contracture difficult to achieve? As *Brooks (1922)* has shown in his experimental studies blockage of the arterial blood circulation of muscles causes either complete necrosis and destruction of the muscle if collateral circulation is insufficient or preservation of the muscle with normal appearance and functioning if collateral circulation is sufficient. Arterial production of ischemic contracture does not succeed in fact. Fibrosis and shortening of the muscle do not occur. *Brooks* states however that obstruction of the purely venous blood circulation does cause fibrosis and muscle shortening and that extravasation of the red corpuscles and disturbed nutrition of tissues cause changes. In the present tests the production of disturbance in the purely venous blood circulation of rabbit muscles was hardly

successful *Clark* (1946) has shown moreover that endomysium remaining after partial experimental ischemic necrosis has astonishing ability to regenerate the endomysial tubes. It is thus understandable that attempts to produce permanent ischemic muscle contracture were unsuccessful.

Soft tissue contracture which develops during plaster immobilisation is a well known clinical phenomenon. Also experimental studies described in the last century produced contractures in striated muscles when they were kept shortened for a certain time by methods including moving the muscle's points of attachment nearer to the origin (*Woll* 1886) or severing the muscle tendon to make the muscle contract. A fixation of the muscle then occurs at the length imposed upon it. This contracture is called myostatic though its pathogenesis has not been fully explained. If immobilisation is interrupted early enough the contracture can be overcome by active or passive movements but if the shortening of a muscle is maintained for some weeks it cannot be immediately extended without structural damage. It has also been shown that this fixation only occurs when muscle innervation is intact (*Frolich* and *Meyer* 1920). The change is more noticeable in growing rabbits than in those of full age when tested (*Crawford* 1954). In growing rabbits muscle growth is so inhibited that shortening remains permanent and full development is never recovered even if immobilisation ceases (*Alder Crawford* and *Edwards* 1959). Some writers maintain that a contracted muscle of this kind is histologically normal (*Ranson* and *Sams* 1928, *Alder Crawford* and *Edwards* 1959) but as *Ferguson Vaughan* and *Ward* (1957) remark the literature contains highly divergent conceptions of the histological changes involved in myostatic contracture. The old physiological law which states that stretched muscles (including fascia and tendons) remain insufficient and that shortened soft tissues contract is applicable to myostatic contracture.

According to the present study plaster immobilisation or other fixation in a certain position such as equinovarus causes a permanent postural deformity in the growing rabbit. After immobilisation of shorter duration the posture and mobility of joints returned to normal and no permanent deformity developed. This makes an interesting comparison with the results obtained by *Ferguson Vaughan* and *Ward* (1957) in their study of disuse atrophy of muscle in rabbits. There appeared to be no essential histological change after two weeks of immobilisation but after four weeks a lesion could be recognized. In the present tests the main issue may be the myostatic contracture of soft tissues already described.

Three to four weeks of immobilisation are scarcely long enough for the development of bone changes which would keep the foot in a deformed position after immobilisation is ceased. The explanation of this may be found in muscle tendon ligament and/or cartilage changes. In the present tests at least, radiological observation has so far revealed no morphological bone changes. These appear later if the position of deformity is maintained.

The permanent deformities achieved by the fixation method in the present study are presumably based on a similar influence they developed when a hind foot was placed in equinus and varus position by means of nylon suture. Tests were performed on 5 day old rabbits and immobilisation was maintained for several weeks. With several test animals in which the thread came loose in the course of a few weeks the deformity did not remain permanent but corrected itself within one week.

It is interesting to compare the results of *Spencer and Peltier* (1964) when they produced plantar flexion and ulnar deviation of the fore foot by means of silk thread in a fetal rabbit 6-7 days before birth. The thread was removed on the day of delivery. Eight rabbits born with deformities lived for more than 3 days and 3 of these lived at least 6 weeks. In all except one the deformity corrected itself within one week after birth. One rabbit had persistent ulnar deviation and X rays of the limb revealed a synostosis of the radius and ulna at the point where the suture had passed through the forearm. In these experiments in fact no permanent deformity provoked by a fixed position remained. Apart from the fact that their rabbits were operated on a few days before birth and in present study a few days after the most noticeable difference is that immobilisation with silk suture lasted only one week in their experiments and over 3 weeks in this investigation. On the basis of my results it was not expected that any permanent deformity would remain and our results are thus parallel.

B TALIPES EQUINOVARUS IN MAN AND IN THE RABBIT

1 Morphological changes in bones

Many common points can be noted when the morphological and pathological anatomical bone changes of talipes equinovarus deformities produced in rabbits are compared with analyses of these deformities in man.

If the experimental club foot deformities produced are examined 2-4 months after operation changes can be noted in the morphology of individual bones as well as in the positions of bones in relation to

each other. These correspond significantly to the bone changes encountered in recently published reports of careful dissections of talipes equinovarus (Becnot and Mossman 1950, Irani and Sierman 1963, Settle 1963, Renarn 1967). The principal change is in the neck of the talus which is deviated medially and plantarward on the body. In addition the navicular articular surface of the talus faces medially and plantarward. The calcaneus is almost normal in contour but somewhat smaller than normal in size. The talonavicular and calcaneocuboidal joints are not in the frontal plane as is normal but turned medially and plantarward. The talo-calcaneal angle is diminished. The navicular is slightly smaller than normal and has moved medially near the medial malleolus in extreme cases. Cuneiforms, cuboides and metatarsals are almost normal in shape and size. The posterior part of the calcaneus is often inclined towards the region of the lateral malleolus where an accessory joint is formed.

2. Soft tissue changes

When the club foot deformities produced in rabbits are examined from the functional point of view changes can be observed similar to those encountered in man. If the Achilles tendon in the rabbit is strongly tightened it can be clearly seen to exert a supinatory action and to cause a slight varus in the sole of the foot. Mere attachment of the Achilles tendon in a week old rabbit causes a tendency towards the same phenomenon which disappears however during growth and with use of the foot. No progressive deformity ensues and further factors are evidently needed for its development in test animals. Mere extensor insufficiency apart from Achilles tension was unable to cause equinovarus deformity in the experiments. Peroneal insufficiency was also required. If severing of the peroneus was combined with fixation of the Achilles tendon the result was varus and slight adduction of the fore foot combined with dorsiflexion rather than equinus. In accordance with this are the club foot dissections of the newborn made by Adams 1855. He found changes in the gastrocnemius, tibialis anterior and tibialis posterior muscles. All three muscle bellies were shortened. In 1959 Wiley noted the same phenomenon in his anatomical studies where in cases of club-foot among small children muscle bellies were shorter and narrower. The principal muscles affected were the gastrocnemius and soleus, tibialis posterior and tibialis anterior.

In examining experimental equinovarus deformities I observed the same phenomenon as Stewart (1951) in his anatomical study of club-foot that the Achilles tendon seems to attach itself to the medial part of the

Three to four weeks of immobilisation are scarcely long enough for the development of bone changes which would keep the foot in a deformed position after immobilisation is ceased. The explanation of this may be found in muscle-tendon ligament and/or cartilage changes. In the present tests at least radiological observation has so far revealed no morphological bone changes. These appear later if the position of deformity is maintained.

The permanent deformities achieved by the fixation method in the present study are presumably based on a similar influence they developed when a hind foot was placed in equinus and varus position by means of nylon suture. Tests were performed on 5 day old rabbits and immobilisation was maintained for several weeks. With several test animals in which the thread came loose in the course of a few weeks the deformity did not remain permanent but corrected itself within one week.

It is interesting to compare the results of *Spencer and Peltier (1964)* when they produced plantar flexion and ulnar deviation of the fore-foot by means of silk thread in a fetal rabbit 6—7 days before birth. The thread was removed on the day of delivery. Eight rabbits born with deformities lived for more than 3 days and 3 of these lived at least 6 weeks. In all except one the deformity corrected itself within one week after birth. One rabbit had persistent ulnar deviation and X rays of the limb revealed a synostosis of the radius and ulna at the point where the suture had passed through the forearm. In these experiments in fact no permanent deformity provoked by a fixed position remained. Apart from the fact that their rabbits were operated on a few days before birth and in present study a few days after the most noticeable difference is that immobilisation with silk suture lasted only one week in their experiments and over 3 weeks in this investigation. On the basis of my results it was not expected that any permanent deformity would remain and our results are thus parallel.

B TALIPES EQUINOVARUS IN MAN AND IN THE RABBIT

1 Morphological changes in bones

Many common points can be noted when the morphological and pathological bone changes of talipes equinovarus deformities produced in rabbits are compared with analyses of these deformities in man.

If the experimental club foot deformities produced are examined 2—4 months after operation changes can be noted in the morphology of individual bones as well as in the positions of bones in relation to

affect their physiology and ability to stretch and contract normally and may be a cause of the recurrence of club-foot deformity

In accordance with the present investigation are the interesting observations by *Flinchum* (1933) on the dissection of a six and a half month fetal club-foot. The contour and relative size of individual bones in the club-foot and the normal foot appeared identical in the fetus at this stage of fetal growth. But the author noted that the Achilles tendon and the tendinous part of the tibialis anterior muscle were longer in the club-foot than in the healthy foot. The tibialis anterior muscle was the only structure which offered abnormal resistance to eversion. The mass of the peroneals on the affected side was only half that on the normal side. He interpreted this as muscular imbalance due to dysplasia of the peroneals.

Hirsch (1960) has noted under operative exposure in his series that in all patients the deltoid ligament was tight, the talus anteriorly displaced and the Achilles tendon medially displaced. In rabbits with equinovarus deformities very tense medial ligamentous contracture could also be found.

C VERTICAL TALUS IN MAN AND IN THE RABBIT

1 Morphological and radiological changes

When experimental talus verticalis deformities were analysed and compared with clinical observations of *Langenskiöld* (1964) remarkable general morphological similarities were found. In clinical examination of a talus verticalis foot in a child and in a rabbit the shape of the foot is conspicuous. There is a prominence in the sole from which the heel and fore part of the foot rise in a gentle curve. The general appearance is like a rocker hence the term rocker foot. The head of the talus is prominent on the plantar aspect of the foot. This is both visible and palpable medially. Later a callus develops and sometimes also an ulceration over the prominent head of the talus. When the fore part of the foot moves into dorsiflexion the distinct convexity is accentuated.

Remarkable similarities have been observed in radiological studies of the skeleton of the foot in children and rabbits with vertical talus. The most important was that the distal portions of the calcaneus and talus rotate towards the plantar surface, the talus rotating into a vertical position. The subtalar joint appear intact with the exceptions that the plane of the joint is more vertical and the talus is further forward on the calcaneus than in the normal foot. There is an abnormal articu-

calcaneus which was inclined to varus. Muscle imbalance combination leading to equinovarus in rabbit also agrees with *Stewart's* proposition a positive deforming force + a negative deforming force. He states that the triceps surae, the tibialis anterior and minor plantar muscles exert a positive deforming force while the peroneus muscles deprived of their postural activity cannot function to inhibit the distortion. Except that the combination of fixation of the Achilles tendon, tenodesis or external transection of peroneus and extensor digitorum longus led to equinovarus deformity it could be noted on the other hand that transection of the tibialis anterior prevented its development. It appeared that the pull of the tibialis anterior was important for the medial dislocation of the navicular and also the beginning of metatarsus varus for after the dissection of the tibialis anterior this transference did not occur. The deforming effect of the tibialis anterior in present tests are in accordance with the observations of *Garceau* and *Manning* (1947) on the imbalance between the invertor and evertor muscles. They recommend the transfer of tibialis anterior more laterally in the tarsus in cases of recurring club foot like many others (*Durbin* 1950, *Critchley* and *Taylor* 1952).

Without going further into the many soft tissue operations which were performed later it may be mentioned that in 1888 *Vincent Jackson* announced a successful cure for congenital club foot immediately after severing the Achilles tendon and the tendons of the tibialis anterior and the tibialis posterior. It was probably *Lorenz* in 1784 however who first severed the Achilles tendon in order to correct club foot. Many others have later recommended the use of a soft tissue operations directed at the release of the contractions of the Achilles tendons and the tendons of the tibialis anterior, the tibialis posterior and the flexor digitorum longus and the capsules and ligaments on the medial side of the foot (*Codivilla* 1906, *Bankart* 1922, *Brockman* 1930, *McCauley* 1959, *Pasila* and *Sulamaa* 1961). My animal experiments are in accordance with these operations.

Observations made by *Bechtol* and *Mossmann* in 1950 on muscle changes after dissection of two club foot fetuses are also consistent with present experimental results. They support the theory that faulty muscle development is an important link in the pathogenetic chain of congenital club foot. The gastrocnemius, soleus, tibialis posterior, flexor hallucis longus and flexor digitorum longus muscles showed the presence of many abnormal embryonic muscle fibres. Failure of these muscles to lengthen at the same rate as the bones of the skeleton may be the cause of the inversion of the foot. Failure in development of these muscles may

merely the ligamentum transversum cruris tightening of the extensor group was more severe than the tibialis anterior so that the final result was of the extensor type. This could also be noted immediately after severing the ligament following which the sole was drawn into abduction and valgus. Herndon and Heyman (1963) said that the foot as a whole is fixed in valgus and cannot be inverted. But Mead and Anast (1961) wrote that the fore foot need not be in valgus as is implied sometimes in the literature. The latter view agrees with present experimental results in which to be sure the extensor type was in valgus in the fore foot but the so called tibialis anterior type showed a tendency towards varus in the fore foot. This is due to the elevation of the first metatarsal secondary to tightening of the tibialis anterior and transference of the point at which the pull is exerted. Franke (1901) has also noted that in congenital flat foot in man the tendon of tibialis anterior was not inserted on the plantar aspect of the first metatarsal and the first cuneiform but on the dorsal surface.

Closer analysis of experimental specimens and operative findings in children showed further similarities in dorsiflexion contracture. In both of the above categories adhesions developed in the tarsus and the peroneal and extensor tendons became so fixed that their normally more distal pull had been transferred to the dorsum pedis in the tarsal region.

D CONCLUSIONS

In this investigation it was possible to produce foot deformities in newborn rabbits phenotypically similar to human congenital foot deformities especially talipes equinovarus and vertical talus deformities by means of surgical and non surgical soft tissue procedures. Apart from equinovarus and vertical talus deformities produced in rabbits other imitations of the foot deformities encountered in children such as talipes equinus, calcaneus and varus, cavus, calcaneovalgus and metatarsovarus have also been similarly produced in rabbits by means of operations on soft tissues. A report will be published later.

An attempt was made to elucidate the peripheral mechanisms of foot deformities in experiments and to compare these with observations in humans. It seemed clear that the talipes equinovarus and vertical talus changes produced in experiments were closely related to mechanical factors. The same procedures could lead to the occurrence of either of the deformities. The talus was in the key position in both and the manner

lation of the navicular with the upper surface of the neck of the talus. In their studies *Hart* (1950) and *Hareson* (1959) have precisely described this phenomenon and its importance in the development of deformity. There is also a widening of the calcaneocuboid joint and the cuboid is somewhat displaced upward at the calcaneocuboid articulation. The calcaneus is in the equinus position and the posterior part of the heel fails to touch the ground on standing. The anterior portion of the calcaneus deviates in a lateral direction. The calcaneus is generally underdeveloped and is convex on its plantar surface. The long axis of the talus the keystone of the deformity is almost in line with the axis of the tibia. This bone becomes narrow at the waist and re-embles an hourglass. A moulding of the navicular occurs later.

2 Soft tissue changes

In vertical talus in rabbits the Achilles tendon was tight. In the opinion of some authors this is not always so in vertical talus in man. It has been a relative phenomenon in some cases in our clinical examinations (*Langenskiöld* and *Ritsila* 1964) at least and can remain unnoticed in routine examination. In the position of deformity with the fore foot in dorsal flexion and abduction the Achilles tendon is not stretched but when the position is corrected to normal the Achilles tendon is seen to tighten so that in these cases too Achilles tautness is present whether it is a primary or secondary factor.

The fore foot of rabbits with vertical talus was in dorsiflexion. This was maintained by the tautness of the soft tissue structures ventral to the ankle. Many authors dealing with vertical talus in man have directed their attention to this dorsiflexion contracture (*Hark* 1950, *Lloyd Roberts* and *Spence* 1958). *Lamy* and *Weissman* (1939) said that the contracted extensor tendons can be felt as prominent and resisting all correction. *Herndon* and *Heyman* (1963) said that the peroneal and extensor tendons may be taut and may resist passive inversion.

Examinations of both rabbits and children with vertical talus reveal as shown earlier that dorsiflexion contractures may exist either in the extensor peroneus group or in the tibialis anterior muscle. Thus it has been possible to distinguish these so called extensor and tibialis anterior types. Both types have also been encountered later in children at operation (*Langenskiöld* 1964). In tests where neither the extensor digitorum longus muscle nor the tibialis anterior muscle was severed but change in their action and myostatic contracture were produced by severing

merely the ligamentum transversum cruris tightening of the extensor group was more severe than the tibialis anterior so that the final result was of the extensor type. This could also be noted immediately after severing the ligament following which the sole was drawn into abduction and valgus. Herndon and Heyman (1963) said that the foot as a whole is fixed in valgus and cannot be inverted. But Mead and Anast (1961) wrote that the fore foot need not be in valgus as is implied sometimes in the literature. The latter view agrees with present experimental results in which to be sure the extensor type was in valgus in the fore foot but the so called tibialis anterior type showed a tendency towards varus in the fore foot. This is due to the elevation of the first metatarsal secondary to tightening of the tibialis anterior and transference of the point at which the pull is exerted. Franke (1901) has also noted that in congenital flat foot in man the tendon of tibialis anterior was not inserted on the plantar aspect of the first metatarsal and the first cuneiform but on the dorsal surface.

Closer analysis of experimental specimens and operative findings in children showed further similarities in dorsiflexion contracture. In both of the above categories adhesions developed in the tarsus and the peroneal and extensor tendons became so fixed that their normally more distal pull had been transferred to the dorsum pedis in the tarsal region.

D CONCLUSIONS

In this investigation it was possible to produce foot deformities in newborn rabbits phenotypically similar to human congenital foot deformities especially talipes equinovarus and vertical talus deformities by means of surgical and non surgical soft tissue procedures. Apart from equinovarus and vertical talus deformities produced in rabbits other imitations of the foot deformities encountered in children such as talipes equinus calcaneus and varus cavus calcaneovalgus and metatarsovarus have also been similarly produced in rabbits by means of operations on soft tissues. A report will be published later.

An attempt was made to elucidate the peripheral mechanisms of foot deformities in experiments and to compare these with observations in humans. It seemed clear that the talipes equinovarus and vertical talus changes produced in experiments were closely related to mechanical factors. The same procedures could lead to the occurrence of either of the deformities. The talus was in the key position in both and the manner

in which the fore foot changed position especially in the talonavicular joint was decisive. In talus verticalis the fore foot moved into dorsiflexion, abduction and eversion. In talipes equinovarus it moved into plantar flexion or equinus, adduction and inversion. *Osmond Clarke* (1956) suggested that club foot is essentially a talonavicular and subtalar subluxation and vertical talus is a subluxation at the same joints but with displacement in the opposite direction. It is interesting that *Herndon and Heyman* (1963) too were inclined to believe that congenital convex pes valgus or vertical talus is closely akin to a club foot in etiology.

The present author has assumed that a peripheral primary fault in different congenital foot deformities which may differ in their etiology is of a similar nature. This peripheral fault may lie in the muscles or other soft tissues. The resultant bony deformity was thus assumed to be extrinsic not intrinsic, secondary not primary. The results confirm these assumptions.

Soft tissue contractures and combinations of them resembling those encountered in man have been produced in rabbits. It has also been verified that they cause corresponding structural deformities of the bones. Thus soft tissue changes have exerted a controlling influence on bone growth evidently following of bone transformation suggested earlier (*Hueter* 1862 v *Vollmann* 1869 *Wolff* 1892).

VI SUMMARY

The aim of this study was to produce in young rabbits imitations of the congenital foot deformities encountered in man by provoking changes in the soft tissues

A total of 76 separate procedures were performed. Approximately 500 rabbits were used. 402 for actual tabulated procedures and the rest for preliminary tests

By means of transections and resections of tendons and muscles tenodeses, transections of ligaments and fixation in plaster in extreme positions it was found possible to produce a number of imitations of foot deformities found in humans, those corresponding to talipes equinovarus and vertical talus are described. The age of the rabbits at operation varied from 4 to 28 days, most of them being from 6 to 7 days old.

Marked talipes equinovarus deformity was produced in 32 rabbits and vertical talus in 51. The course of development of the deformity was followed during growth by repeated radiography. The deformities produced were analyzed by dissection and photography of the feet of 75 animals killed at different ages. Sections for histological examination were taken from 8 animals.

In both a macro- and micro-anatomical and a radiological sense, great similarities were observed between the deformities in rabbits and those encountered in humans.

Talipes equinovarus was produced by operation on the soft tissues by using only a combination of Achilles tenodesis, transection of the extensor digitorum longus muscle and transection of both peroneal muscles. Sufficiently long immobilisation in the equinovarus position 3-4 weeks also led to a permanent even progressive equinovarus deformity. A resemblance in general structure between such deformities in rabbits and humans was noted (Fig. 4, p. 34) including the interrelation of bones of the feet (Figs 5, 6, 7, p. 36-37), the radiological examination (Figs 9, 10, p. 38-39), the changes in the shape of individual bones (Figs 11, 12, p. 41-42), the changes in soft tissues (Fig. 13, p. 43) and the microscopic examination (Fig. 14, p. 47).

Vertical talus deformity was produced most easily by causing simultaneous contracture of the triceps surae muscle group and the dorsiflexor muscles of the foot. Myostatic contracture was caused by plaster or other immobilisation and transection of the ligamentum transversum cruris or Achilles tenodesis was used instead of the triceps surae contracture provoked by immobilisation in the equinus position. By combining these measures with transections of either the tibialis anterior or the extensor digitorum longus on the dorsiflexor side of the foot two separate types of vertical talus deformity were produced. These two types have also been discerned in a series of vertical talus feet in children (*Langenskiöld* 1964). Similarities have also been noted in the general structure of experimental vertical talus deformities in rabbits and human vertical talus deformities (Figs 17, 18, 19, 20 pp 54-55) and in the interrelation of bones (Figs 21, 22, 23 pp 57, 58, 59). In the same way radiological comparison (Figs 24, 25, 26, pp 61, 62, 63) and comparison of the shape of the talus (Figs 27, 28 pp 65, 66) in relation to descriptions given in the literature show distinct similarities. Muscular and ligamentous contracture of the vertical talus in rabbits and in humans was found to be very similar (Fig 29 p 69). A resemblance was also noted in the microscopic comparison (Fig 30 p 70).

The results of the present study confirm the importance of considering primary soft tissue changes as a factor provoking secondary skeletal deformities.

Vertical talus deformity was produced most easily by causing simultaneous contracture of the triceps surae muscle group and the dorsiflexor muscles of the foot. Myostatic contracture was caused by plaster or other immobilisation and transection of the ligamentum transversum cruris or Achilles tenodesis was used instead of the triceps surae contracture provoked by immobilisation in the equinus position. By combining these measures with transections of either the tibiis anterior or the extensor digitorum longus on the dorsiflexor side of the foot two separate types of vertical talus deformity were produced. These two types have also been discerned in a series of vertical talus feet in children (Langenskiöld 1964). Similarities have also been noted in the general structure of experimental vertical talus deformities in rabbits and human vertical talus deformities (Figs 17 18 19, 20 pp 54 55) and in the interrelation of bones (Figs 21 22 23 pp 57 58 59). In the same way radiological comparison (Figs 24 25 26 pp 61 62 63) and comparison of the shape of the talus (Figs 27 28 pp 65 66) in relation to descriptions given in the literature show distinct similarities. Muscular and ligamentous contracture of the vertical talus in rabbits and in humans was found to be very similar (Fig 29 p 69). A resemblance was also noted in the microscopic comparison (Fig 30, p 70).

The results of the present study confirm the importance of considering primary soft tissue changes as a factor provoking secondary skeletal deformities.

APPENDIX

Seven series of pictures describing development and progression of the talipes equinovarus and vertical talus deformities produced by various procedures in newborn rabbits

In each picture from left to right normal foot in lateral projection deformed foot in lateral projection normal foot in dorsoplantar projection and deformed foot in dorsoplantar (or antero-posterior) projection

FIG. 31. Development and progression of the talipes equinovarus deformity in a rabbit. Series XXVI no. 10.

Top: lateral and dorsoplantar roentgenograms one week after Achilles tenodesis, transection of the extensor digitorum longus and peroneal muscles, and transection of the ligamentum transversum cruris.

Centre: six weeks; bottom: six months after operation.

FIG. 3 Development and progression of the talipes equinovarus deformity in a rabbit produced by plaster immobilisation in equinovarus position Series LIX no. 1

Top lateral and plantar roentgenogram, one week after immobilisation

Centre six weeks bottom six months after immobilisation immobilisation removed

FIG. 31. Development and progression of the talipes equinovarus deformity in a rabbit Series XXXI no. 10.

Top: lateral and dorsoplantar roentgenograms one week after Achilles tenodesis, transections of the extensor digitorum longus and peroneal muscles and transection of the ligamentum transversum cruris.

Centre: six weeks. Bottom: six months after operation.

FIG 32 Development and progression of the talipes equinovarus deformity in a rabbit produced by plaster immobilisation in equinovarus position Series IIX no 1

Top lateral and dorsoplantar roentgenograms one week after immobilisation
 Centre six week bottom six months after immobilisation immobilisation removed

FIG. 33 Development and progression of the talipes equinovarus deformity in a rabbit produced by fixation with nylon thread in equinovarus position. Series XII no 7

Top lateral and dorsoplantar roentgenograms one week after fixation
 Centre six weeks bottom six months after fixation fixation removed

FIG 34 Development and progression of the vertical talus deformity in a rabbit
The extensor digitorum type Series VII no 2

Top lateral and dorsoplantar (or anteroposterior) roentgenograms one week after Achilles tenodesis transections of the tibialis anterior muscle and the ligamentum transversum cruris

Centre six weeks bottom six months after operation

FIG. 35 Development and progression of the vertical talus deformity in a rabbit
the tibialis anterior type Series II no.

Top lateral and dorsoplantar (or anteroposterior) roentgenograms one week after Achille tenodesis, transections of the extensor digitorum longus and peroneal muscles and transection of the ligamentum transversum cruris.

Centre six weeks after operation. Bottom six months after operation.

FIG. 3. Development and progression of the vertical talus deformity in a rabbit produced by plaster immobilisation in equinus position and transection of the ligamentum transversum cruris. Series I VI no. 3.

Top: lateral and dorsoplantar roentgenograms one week after operation.
 Centre: six weeks. Bottom: six months after operation.

FIG. 37 Development and progression of the vertical talus deformity in a rabbit produced by fixation with nylon thread in equinus position. Series VII no. 6
 Top: lateral and dorsoplantar roentgenograms one week after fixation
 Centre: six weeks after fixation
 Bottom: six months after fixation, fixation removed

PREFACE

My sincere thanks are due to all those whose help in a variety of ways has been a prerequisite for realization of this investigation

To Professor John Sevastikoglou Head of the Department of Orthopaedic Surgery, University Hospital Umeå my chief and teacher who originally suggested the subject of this study for his personal interest and for generous aid in planning and carrying through the investigation

To Professor Tor Hiertonn Head of the Department of Orthopaedic Surgery University Hospital Uppsala for the years spent in the stimulating atmosphere of his clinic

To Professor Bengt Enbfeldt Head of the Institute of Pathology University of Uppsala for the privilege of using his laboratory facilities for the work on bone glycosaminoglycans

To Docent Sven Olof Hjertquist for generous help in methodological questions in the work on bone glycosaminoglycans

To Docent Rudolf Lemperg for helpful criticism and advice

To Laborator Karl Johan Öbrink and Docent Coran Östling Institute of Physiology, University of Uppsala for technical aid in Ca^{45} activity determinations

To Lennart Gustafsson F.K. for valuable help with the statistics

To Miss Maud Marsden for correction of the use of the English language

The work was supported by grants from the Swedish Medical Research Council King Gustaf the Fifth's Eightieth Birthday Fund The Faculty of Medicine University of Uppsala and the Faculty of Medicine University of Umeå Sweden

INTRODUCTION

DEFINITION

The definition of osteoporosis is the least controversial aspect of an otherwise highly controversial subject (Rose 1967). According to the generally accepted definition osteoporosis is a condition resulting from a widespread lack of bone with no detectable chemical abnormality in the bone that remains (Albright and Reifenstein 1948, Nordin 1961, Lafferty et al 1964, Dent and Watson 1966, Rose 1967). Although this definition has never been seriously challenged there are reports according to which it would not hold true. Thus osteoporotic bone has been found to show cellular differences from the normal i.e. an increased frequency of devitalized osteocytes and empty lacunae (Urist et al 1963) and disturbed bone cell metabolism as measured *in vitro* (Nichols Jr and Flanagan 1966). A slight but definite reduction in the calcium content and the Ca/P ratio of osteoporotic bone has been reported by Birkenhaefer Frenkel et al (1961). Results of studies on the composition of microscopic bone structures from human material of varying ages indicate changes in the contents of calcium, phosphorus and nitrogen measured as percentage by weight (Strandh and Narlen 1965). Changes in organic bone matrix have been reported from studies with the aid of X-ray diffraction and electron microscopy (Little et al 1962). In osteoporotic subjects decreased hydroxyproline contents have been found in bone specimens from the iliac crest (Birkenhaefer Frenkel 1966). Biochemical studies (Cassuto et al 1962) indicate a decrease with age in protein, collagen and polysaccharides and changes in the glucosamine/galactosamine ratio in fractions of vertebral bone tissue extracted according to Diche et al (1958). The qualitative changes in bone matrix observed by Little et al (1962) and Cassuto et al (1962) have been related to the osteoporotic process. The significance of this as a pathophysiological mechanism remains to be determined however.

PREFACE

My sincere thanks are due to all those whose help in a variety of ways has been a prerequisite for realization of this investigation

To Professor John Sevastikoglou Head of the Department of Orthopaedic Surgery, University Hospital, Umeå my chief and teacher who originally suggested the subject of this study for his personal interest and for generous aid in planning and carrying through the investigation

To Professor Tor Hiertonn Head of the Department of Orthopaedic Surgery, University Hospital Uppsala for the years spent in the stimulating atmosphere of his clinic

To Professor Bengt Engfeldt Head of the Institute of Pathology University of Uppsala for the privilege of using his laboratory facilities for the work on bone glycosaminoglycans

To Docent Sven Olof Hjertquist for generous help in methodological questions in the work on bone glycosaminoglycans

To Docent Rudolf Lemperg for helpful criticism and advice

To Laborator Karl Johan Öbrink and Docent Goran Östling Institute of Physiology University of Uppsala for technical aid in Ca^{45} activity determinations

To Lennart Gustafsson F.K. for valuable help with the statistics

To Miss Maud Marsden for correction of the use of the English language

The work was supported by grants from the Swedish Medical Research Council King Gustaf the Fifth's Eightieth Birthday Fund The Faculty of Medicine University of Uppsala and the Faculty of Medicine University of Umeå Sweden

In hypogonadism osteoporosis may occur both in males and females (Albright *et al* 1942) and the hypothesis that oestrogen deficiency is the cause of human osteoporosis was advanced by Albright and Reifenstein (1948). This hypothesis was extended later to include the possibility that senile and other forms of osteoporosis are caused by an imbalance between anabolic or gonadal hormones and anti anabolic or adrenal corticoid hormones (Reifenstein 1957 Urist and Vincent 1960). The role of the menopause in the occurrence of osteoporosis has been emphasized by radiological observations of a fall in bone density corresponding in time to the menopause (Jasani *et al* 1965 Meema *et al* 1965 Meema 1966 Nordin *et al* 1966). However only a low degree of correlation was found by Saville (1967) in a study of women who had had a surgical and women with a natural menopause. The menopause would then be only one of different factors of importance for the occurrence of osteoporosis. The original concept of Albright *et al* (1940) that involutional osteoporosis is due to osteoblastic failure consequent to a deficiency of gonadal hormones has been made unenable by results of more recent investigations with refined morphological techniques and of calcium balance and radiocalcium kinetic studies. It has been concluded from results of these studies that new bone formation is commonly normal in postmenopausal and senile osteoporosis (Heaney and Whedon 1958 Nordin 1960) and that osteoblastic activity does not diminish with age (Jowsey 1960 Frost and Villanueva 1961). Instead bone resorption appears to be markedly increased in osteoporosis (Frost 1961 Riggs *et al* 1964).

Hypercorticism of endogenous origin is often associated with osteoporosis (Albright and Reifenstein 1948 Fallis 1951 Iannaccone *et al* 1960 Storey 1963). In prolonged cortisone therapy osteoporosis is a serious complication (Burrows *et al* 1955 Reifenstein 1958 Rosenberg 1958) however there are reports suggesting that the contribution of other factors may be necessary for the development of corticosteroid osteoporosis. Thus 85 per cent of the patients of comparable ages and skeletal conditions do not develop osteoporosis on comparable steroid therapy (Schlesinger *et al* 1961). It has not been possible to relate the incidence of fractures to the dose of steroids or to the duration of treatment (McConkey *et al* 1962). In patients with allergic diseases treated with steroids only a small effect on the skeleton has been reported (Krokowski and Stresemann 1967).

Of the nutritional disturbances scurvy leads to radiological signs of osteoporosis in adults and has recently been studied in Johannesburg Bantu (Seftel *et al* 1966). However the clinical picture in these subjects is confused by the presence of hepatic siderosis and other factors (Dent and Watson 1966).

CLINICAL OSTEOPOROSIS

Osteoporosis is not a single disease entity but is a condition produced by many different factors (Frost 1963). Despite the varying aetiology the end result — osteoporosis — is now a well recognized condition and justifies its description by a single term (Dent and Watson 1966). In the following table the main causes have been listed according to Rose (1967).

THE MAIN CAUSES OF OSTEOPOROSIS

- 1 Endocrine disturbances
 - Hypogonadism
 - Cushing's syndrome
 - Cortisone administration
 - Acromegaly
 - Thyrototoxicosis
- 2 Nutritional disturbances
 - Scurvy
 - Calcium deficiency
 - Protein deficiency
- 3 Idiopathic
 - Juvenile
 - Pregnancy
 - Postmenopausal
 - Senile
- 4 Inherited
 - Osteogenesis imperfecta
- 5 Immobilization

In the numerous attempts made in the past to find the aetiological agents which could provide the clues to the pathogenesis of idiopathic osteoporosis endocrine and nutritional disturbances have been extensively studied in this respect.

Of the endocrine disturbances thyrotoxicosis is considered by some authors to give rise to osteitis fibrosa rather than osteoporosis (Follis 1953, Rose 1967). In acromegaly the predominant bone disorder does not seem to be osteoporosis but a change in distribution of spongy and compact bone in the skeleton (Jesserer 1961).

In hypogonadism osteoporosis may occur both in males and females (Albright et al 1942) and the hypothesis that oestrogen deficiency is the cause of human osteoporosis was advanced by Albright and Reifenstein (1948). This hypothesis was extended later to include the possibility that senile and other forms of osteoporosis are caused by an imbalance between anabolic or gonadal hormones and anti-anabolic or adrenal corticoid hormones (Reifenstein 1957 Urist and Vincent 1960). The role of the menopause in the occurrence of osteoporosis has been emphasized by radiological observations of a fall in bone density corresponding in time to the menopause (Jasani et al 1965 Meema et al 1965 Meema 1966 Nordin et al 1966). However only a low degree of correlation between age at the menopause and age at the onset of symptomatic osteoporosis was found by Seftel (1967) in a study of women who had had a surgical and women with a natural menopause. The menopause would then be only one of different factors of importance for the occurrence of osteoporosis. The original concept of Albright et al (1940) that involutional osteoporosis is due to osteoblastic failure consequent to a deficiency of gonadal hormones has been made untenable by results of more recent investigations with refined morphological techniques and of calcium balance and radiocalcium kinetic studies. It has been concluded from results of these studies that new bone formation is commonly normal in postmenopausal and senile osteoporosis (Heaney and Whedon 1958 Nordin 1960) and that osteoblastic activity does not diminish with age (Jowsey 1960 Frost and Villanueva 1961). Instead bone resorption appears to be markedly increased in osteoporosis (Frost 1961 Riggs et al 1964).

Hypercorticism of endogenous origin is often associated with osteoporosis (Albright and Reifenstein 1948 Follis 1951 Iannaccone et al 1960 Storey 1963). In prolonged cortisone therapy osteoporosis is a serious complication (Burton et al 1955 Reifenstein 1958 Rosenberg 1958) however there are reports suggesting that the contribution of other factors may be necessary for the development of corticosteroid osteoporosis. Thus 85 per cent of the patients of comparable ages and skeletal conditions do not develop osteoporosis on comparable steroid therapy (Schlesinger et al 1961). It has not been possible to relate the incidence of fractures to the dose of steroids or to the duration of treatment (McConkey et al 1967). In patients with allergic diseases treated with steroids only a small effect on the skeleton has been reported (Arokowicz and Stresemann 1967).

Of the nutritional disturbances scurvy leads to radiological signs of osteoporosis in adults and has recently been studied in Johannesburg Bantu (Seftel et al 1966). However the clinical picture in these subjects is confused by the presence of hepatic siderosis and other factors (Dert and Watson 1966).

CLINICAL OSTEOPOROSIS

Osteoporosis is not a single disease entity but is a condition produced by many different factors (*Frost 1963*) Despite the varying aetiology the end result — osteoporosis — is now a well recognized condition and justifies its description by a single term (*Dent and Watson 1966*) In the following table the main causes have been listed according to *Rose (1967)*

THE MAIN CAUSES OF OSTEOPOROSIS

- 1 Endocrine disturbances
 - Hypogonadism

The original concept of Albright et al (1940) that involutional osteoporosis is due to osteoblastic failure consequent to a deficiency of gonadal hormones has been made untenable by results of more recent investigations with refined morphological techniques and of calcium balance and radiocalcium kinetic studies. It has been concluded from results of these studies that new bone formation is commonly normal in postmenopausal and senile osteoporosis (Heaney and Whedon 1958, Nordin 1960) and that osteoblastic activity does not diminish with age (Jowsey 1960, Frost and Villanueva 1961). Instead, bone resorption appears to be markedly increased in osteoporosis (Frost 1961, Riggs et al 1964).

Hypercorticism of endogenous origin is often associated with osteoporosis (Albright and Reifenstein 1948, Follis 1951, Iannaccone et al 1960, Storey 1963). In prolonged corticoid therapy osteoporosis is a serious complication (Burton et al 1955, Reifenstein 1958, Rosenberg 1958), however, there are reports suggesting that the contribution of other factors may be necessary for the development of corticosteroid osteoporosis. Thus 85 per cent of the patients of comparable ages and skeletal conditions do not develop osteoporosis on comparable steroid therapy (Schlesinger et al 1961). It has not been possible to relate the incidence of fractures to the dose of steroids or to the duration of treatment (McConkey et al 1962). In patients with allergic diseases treated with steroids only a small effect on the skeleton has been reported (Arokowski and Stresemann 1967).

Of the nutritional disturbances scurvy leads to radiological signs of osteoporosis in adults and has recently been studied in Johannesburg Bantu (Seftel et al 1966). However, the clinical picture in these subjects is confused by the presence of hepatic siderosis and other factors (Dent and Watson 1966).

Protein deficiency has been alleged to cause osteoporosis in humans. However, in the majority of subjects the bone lesion appears to be both osteoporosis and osteomalacia due to lack of vitamins as well as other deficiencies (Jesserer 1963).

The role of pure calcium deficiency in the pathogenesis of osteoporosis is controversial. Albright and Reifenstein (1948) and Rose (1967) among others have considered that specific calcium deficiency is not of primary aetiological importance while other authors (Whedon 1959, Nordin 1960, Fraser 1962) have emphasized the possible role of dietary calcium in the pathogenesis. Although some dietary surveys have shown a normal calcium consumption in osteoporotic persons (Urist 1960, Smith and Frame 1965) and little relation between mild osteoporosis and calcium intake (Nordin 1964) other studies have shown a lower mean calcium intake in osteoporotic than in normal persons (Nordin 1961, Lusaak 1964) and that severe osteoporosis only seems to occur in individuals on a low calcium intake (Nordin 1964). However, man has a considerable ability to adapt to restricted calcium intake by enhanced intestinal absorption or by decreased urinary excretion (Malm 1958) and therefore any further loss of bone mineral might be prevented unless a failure of adaptation to the low calcium level occurs. Some persons are however unable to adapt to calcium restriction and in these subjects a protracted negative calcium balance results (Malm 1958). The nature of this adaptation mechanism is unknown. It seems however that osteoporotic patients are less able than normal subjects to reduce their urinary calcium (Bhandarkar and Nordin 1962) and calcium excretion appears to be independent of the intake in osteoporosis (Nordin 1961). The observed calcium requirement appears to be increased in osteoporosis (Nordin 1962).

During the adult life span there is a gradual decrease in bone mass which occurs more or less physiologically in all normal people. Thus there is a steady loss of apparent density of whole bones from 20 years on in both sexes and in both white and negro races (Trotter *et al.* 1960). These observations were confirmed by Lindahl and Lindgren (1962) who found a parallel decrease in bone density in the upper end of the tibia and the vertebral column with increasing age. The radiographic density of bone removed at autopsy has also been reported to decrease steadily after the age of 20 years in both sexes (Caldwell 1962). In agreement with these findings are those of Arnold (1964) who showed a steady decrease from the age of 30 years in the weight of ash per unit volume of bone removed at autopsy from the lumbar vertebral cortex. From 20 years on there is in both sexes a progressive increase in resorption spaces in the cortical bone (Atkinson 1965). These observations might indicate

a physiological progressive loss of bone in all normal people with increasing age probably due to increased bone resorption. Of importance for this process is certainly the more sedatory life of old people than at younger ages. Osteoporosis due to immobilization is well known. It is not considered however that a more sedatory life is the prime aetiological factor in the pathogenesis rather it might be secondary to symptomatic osteoporosis and induce an additional loss of bone mineral.

From the above findings *Rose (1967)* drew the conclusion that osteoporosis is a condition towards which all people progress gradually beginning soon after the age of 20 years. However according to *Dent and Watson (1966)* symptomatic osteoporosis is caused by the action of an additional process which accelerates this gradual loss of bone resulting in greatly increased negative calcium balances of the order of 200—400 mg per day until the process limits itself spontaneously. This additional process which is of uncertain origin thus causes acute attacks of osteoporosis and these can be observed in the young, the adult and also the senile patient (*Dent 1968*). *Urist (1959)* attributed osteoporosis to the absence of a purported anti osteoporosis factor. The loss of bone mass in normal aging is obviously much slower than in osteoporosis (*Urist 1959*).

In an attempt to incorporate the numerous both unrelated and contradictory observations in osteoporotic patients into a unified concept of osteoporosis *Heaney (1965)* related the osteoporotic process to calcium metabolism and to the demands placed upon the homeostasis of the extracellular fluid calcium. According to this concept dietary calcium deficiency and the intestinal malabsorption syndromes may produce osteoporosis simply by presenting the organism with less mineral than is needed for minimal losses; osteoporosis results because of homeostatic efficiency. Relative or absolute deficiency of gonadal hormones would lead to a negative calcium balance because of increased bone resorption not so much because these hormones decrease resorption *per se* but because they appear to moderate the resorptive response of osteoclasts to homeostatic stimuli and in their absence bone becomes hyperresponsive to parathyroid hormone (*Heaney 1965*).

ANIMAL EXPERIMENTS

Calcium deficiency

There are several reports indicating that osteoporosis can be induced in animals by dietary calcium deficiency. Attempts to produce rickets in animals by feeding

low calcium diets were made in the middle of the last century. In 1885 *Pommer* described for the first time the characteristic features of rickets. In a review article he concluded that low calcium diets caused osteoporosis not rickets (*Pommer* 1925). In a later review of the subject in 1948 *Follis* noted that rickets had been produced by low calcium diets but that no descriptions were available for animals fed diets containing optimal amounts of vitamin D. More recently *Nordin* (1960) in a review, intended to show that osteoporosis could be produced in animals by a negative calcium balance, usually induced by low calcium diets. However only young growing animals were studied in these experiments. There were only two reports of the histological appearance of the bones resulting from a diet deficient solely in calcium where adequate amounts of vitamin D were provided (*Crawford et al* 1957 *Harrison and Fraser* 1960).

While young rats maintained on low calcium diets with adequate amounts of vitamin D have been reported to develop osteoporosis (*Crawford et al* 1957, *Harrison and Fraser* 1960) there are also reports that young growing rats fed a similar diet develop skeletal changes typical of rickets (*Park et al* 1922 *Hess* 1929 *Caritar et al* 1950 *Engfeldt et al* 1962 *Gershon Cohen et al* 1962 *McClendon and Blaustein* 1965). The experiments of *Gershon Cohen et al* (1962) suggest that low calcium diets produce rachitic lesions in the young growing rat but that when the animals attain an adult age the condition is transformed into osteoporosis. Weaned rats maintained on low calcium diets for a certain period of time show signs of rickets but this changes later into osteoporosis without an alteration of diet (*McClendon and Blaustein* 1965). It is therefore considered erroneous to relate the bone lesions induced in young growing rats to osteoporosis as has been done earlier by *Crawford et al* (1957) *Harrison and Fraser* (1960) and *Fraser* (1962). Moreover calcium deficiency in young animals interferes with skeletal growth because a normal calcium intake is necessary for the growth of all tissues including bone regardless of whether other conditions necessary for calcification are present or not (*Caritar et al* 1950 *Toothill and Hosking* 1968).

The adult rat is considered to be resistant to the development of osteoporosis by restricted calcium intake because of its effective adaptation to a low calcium level reported in calcium balance studies (*Nicolaysen et al* 1953). There are however no earlier reports confined to studies on the effect of prolonged calcium deficiency on the skeleton of the adult rat or the pathomechanisms responsible for the skeletal changes induced by such treatment.

Studies with bone seeking isotopes are inconclusive with regard to the skeletal reaction of experimental animals to prolonged calcium restriction. Thus a greater retention than normal of a dose of strontium was reported by Harrison and Fraser (1960) while Copp and Suker (1962) found a reduced retention of Ca^{45} in young rats after dietary calcium restriction. In calcium deficient adult rats the data obtained indicated normal Ca^{45} retention and increased bone resorption as compared with normal controls (Copp and Suker 1962). In this study the bone tissue was not studied further however.

In adult cats fed a low calcium meat diet i.e. calcium 0.007 and phosphorus 0.18 per cent on a wet weight basis radiological evidence of osteoporosis was found after 10 weeks (Jowsey and Gershon Cohen 1964). The bone changes induced were described as osteoporosis. However the appearance of resorption cavities in the cortical bone and the observed increase in number of newly formed osteones together with the described parathyroid hyperplasia suggest that the observed bone lesion would have been osteomalacia or osteitis fibrosa rather than osteoporosis. This is supported by the fact that young growing dogs receiving a low calcium diet with vitamin D supplements develop erosion and resorption of bone with increase in the amount of fibrous tissue associated with the bones (Campbell and Douglas 1965). Similar observations have also been reported in mature dogs maintained on a low calcium high phosphorus diet. In this study the condition was called nutritional hyperparathyroidism (Sattile and Arook 1968). In a recent study on adult cats fed the low calcium high phosphorus meat diet described above an evident but transient osteomalacia was reported at 5 months on the low calcium diet while after 13 months the condition had changed into osteoporosis. Also in these animals secondary hyperparathyroidism occurred (Jowsey and Raisz 1969). These reports indicate that the reaction of the skeleton to prolonged calcium restriction is still poorly understood and that a possible relationship between calcium deficiency and development of osteoporosis in adult mammals needs further investigation.

Treatment with corticosteroids

Animal experiments have also been used for the study of osteoporosis induced by hormonal disturbances. Thus osteoporosis has been reported in young rabbits after cortisone treatment (Sissons and Hadfield 1955 Storey 1957 and 1960). The similarity of these lesions to those observed in Cushing's disease was pointed out by Sissons (1961). From histological observations it was deduced that the

effect of cortisone is inhibitory to new bone formation and that the bone rarefaction is due to unopposed continuance of the normal osteolytic processes (Sissons and Hadfield 1955, Sissons 1956) More recently it has been concluded from morphological studies that the cortisone osteoporosis in rabbits occurs not only from a cessation of bone formation but primarily from a direct degrading effect which causes a massive resorption of bone (deValderrama and Munuera 1966)

The results reported from studies on the effect of cortisone on the skeleton of young growing rats are not conclusive Observed dense metaphyseal bone was believed to be due to delayed bone resorption (Follis 1951) Later it was reported that osteoporosis occurred only when the cortisone treated young rats were fed a diet containing a normal or lowered amount of calcium and phosphorus (Storey 1960) Osteoporosis has also been reported in growing male rats after prolonged cortisone therapy (Kahn and Skoryna 1959)

In growing male rats osteoporosis has been claimed to result from a combination of bilateral adrenalectomy orchidectomy and cortisone administration (Caldwell 1962) Administration of oestradiol cured the osteoporotic changes in these animals despite continued treatment with cortisone while administration of testosterone resulted in only very slight improvement These results suggest that this radiographically observed osteoporosis might have been caused by an excess of corticosteroids in the absence of oestradiol However since young animals were used the interference of the treatment with normal skeletal growth and development makes it difficult to interpret the results obtained

In adult cortisone treated rats the collagen content of the whole femur has been reported to be unchanged while the hexosamine content was decreased This led to the suggestion that a decrease of mucopolysaccharides precedes the events which give rise to osteoporosis in Cushing's disease (Sobel and Marmorston 1954) Although changes in the hexosamine content of the whole femur must reasonably be considered as non representative of the mucopolysaccharides of the bone tissue itself this observation provides considerable interest but needs further investigation

The well known effect of corticosteroids upon the calcium metabolism must further be taken into consideration in studies concerning the pathogenesis of cortisone osteoporosis (Heaney 1965) The skeletal retention of bone seeking isotopes in young growing rats has been reported to be inhibited by the administration of corticosteroids (Clark et al 1959 Milbrand et al 1960 Bohr and Dawids 1964) Calcium excretion has consistently been found to be increased The results reported concerning the effect on intestinal calcium absorption are

not quite conclusive however. The administration of hydrocortisone to young rats has been considered to inhibit the uptake by bone of Ca^{45} which was also found to be decreased in nephrectomized rats. This led to the suggestion that the limiting factor may lie in the synthesis of chondroitin sulphate (Clark *et al* 1959). No reports have been found regarding the effect of combined oophorectomy and prednisolone administration on mature bone tissue.

In the majority of the experimental studies reviewed young growing animals have been used and an interference between the well known growth inhibitory effect of corticosteroids and the skeletal reaction to the treatment cannot therefore be eliminated. The effect of such treatment upon the adult skeleton in which calcification and growth are completed awaits further investigation especially with regard to the development of osteoporosis.

SUMMARIZING REMARKS

- 1 Although osteoporosis is a condition with a clear and generally accepted definition there are reports indicating that this definition can no longer be considered adequate. Thus cellular differences between osteoporotic and normal bone have been observed by morphological and *in vitro* metabolic studies. Changes in the bone minerals have been reported from macro- and microchemical studies. Finally changes in organic bone matrix have been found by physical and biochemical methods.
- 2 In the numerous attempts made to elucidate the aetiological factors connected with the pathogenesis of osteoporosis nutritional and hormonal disturbances have been studied and considered to cause the condition. The opinions expressed in this respect are controversial.
- 3 During the normal aging of the adult skeleton there is a slow, steady loss of bone probably due to a slight increase in bone resorption.
- 4 The opinion has been held that this steady loss of bone during normal aging is the prime aetiological factor for the pathogenesis of osteoporosis.
- 5 Another opinion is that clinical osteoporosis is caused by certain aetiological factors responsible for an acceleration of the normal rate of bone loss for a limited period of time.

6 Although these additional agents are still unknown nutritional and hormonal disturbances must be taken into consideration The effects on the adult skeleton of prolonged calcium restriction and an imbalance between gonadal and adrenal corticoid hormones need further investigation

7 In the pathogenesis of osteoporosis the concept of deficient new bone formation and osteoblastic failure has been abandoned Instead increased bone resorption is considered to be the predominant feature in most of the osteoporoses

8 In a unified concept of osteoporosis disturbed calcium homeostasis is considered to be the main pathophysiological mechanism responsible for induction of different osteoporoses This theory needs further proof however

9 In numerous experiments different bone lesions have been reported by maintaining animals on low calcium diets for certain periods of time The reaction of the adult skeleton to prolonged calcium restriction is however still poorly understood

10 In rabbits osteoporosis can be produced by cortisone treatment In growing rats it occurs only with normal or low intakes of calcium and phosphorus during cortisone treatment In growing animals the inhibitory effect of corticosteroids on growth interferes with the skeletal reaction to the treatment This interference must be taken into consideration especially when its relation to the development of osteoporosis is concerned

11 In adult rats there are no reports of osteoporosis produced by corticosteroids While no effect has been found on the hydroxyproline content of the whole bone the suggested decrease in the concentration of mucopolysaccharides has been related to the development of osteoporosis This needs to be investigated further

12 In growing male rats roentgenological osteoporosis develops after combined bilateral adrenalectomy orchidectomy and cortisone administration Contrary to the experience in clinical osteoporosis the skeletal lesions induced by this treatment could be cured by oestradiol Further studies regarding the reaction of the adult skeletal tissue to hormonal imbalance e.g. excess corticosteroids and lack of gonadal hormones would seem justified therefore

13 Studies on the effect of these nutritional and hormonal disturbances upon calcium homeostasis in the adult animal appear to be of interest in the pathogenesis of osteoporosis

THE PRESENT INVESTIGATION

Concerning the pathogenesis of human osteoporosis prolonged dietary calcium deficiency and imbalance between gonadal and adrenal corticoid hormones have received the greatest interest. The lack of coherent information on the effect of these disturbances upon the adult skeletal tissue with regard to the development of the condition motivated the present investigation. Most previous experimental studies have been performed on young animals whereas osteoporosis is characteristically a disorder of old age. While in clinical osteoporosis most of our present knowledge concerns the different features of the osteoporotic skeleton and not the development of the condition in interpreting most earlier studies of experimental osteoporosis the interference of the induced disturbances with normal skeletal growth and development must be considered.

CHOICE OF EXPERIMENTAL ANIMAL

The adult laboratory rat was used in the present investigation mainly because in this species the minimal calcium need for equilibrium is well defined for different ages. Furthermore in this species the adaptation to restricted calcium intake has been extensively studied by calcium balance techniques. In principle the results of these studies agree with the observations made in humans (Nicolaysen et al. 1953). The laboratory rat is further less liable to uncontrolled variation than man. While in the rat the relation of different induced disturbances to the development of osteoporosis can be studied under well defined experimental conditions in man such possibilities are either restricted or non-existent. The fact that complete closure of some of the epiphyseal zones does not occur in the rat, does not necessarily mean that there is continued active skeletal growth in the adult animal. Thus it has been reported that in the adult rat the epiphyseal cartilages are inactive (El Maraghi et al. 1965). During the first 6 months of life calcification of bone is rapid and remains

steady thereafter (*Henry and Kon 1953*) Moreover, the uptake of radioactive calcium in bones of rats diminishes rapidly from the ages of 3 to 6 months and then decreases only little with age in accordance with measurements of growth rate determined by repeated labelling with tetracycline (*Bohr 1968*) Only rats stated to be 11½ to 12½ months old at the start of the experiment were used in the present investigation except for the animals of one special control group where older rats were used To ensure that the skeleton was fully mineralized at the start of the experiment all rats had been bred on an optimum intake of calcium and phosphorus i.e. 1.4 per cent Ca and 1.2 per cent P, and adequate amounts of vitamin D

PURPOSE OF THE INVESTIGATION

The aim of the present investigation was to determine in adult rats whether or not disturbances induced by a) prolonged calcium restriction and b) oophorectomy combined with prolonged prednisolone administration resulted in changes of the mature bone tissue and calcium metabolism which could be related to the development of osteoporosis according to the definition of *Albright and Peifenstein (1948)* Further the studies were planned with the purpose of following the sequence of changes in various parameters which could be related to the development of the disorder

The results reported herewith will concern the following specific relationships

- I The effect of prolonged calcium restriction on the skeletal tissue of adult male rats
- II The effect of prolonged calcium restriction on the blood calcium level and the distribution of Ca^{45} between blood and bone in adult male rats
- III The effect of combined oophorectomy and prolonged prednisolone administration on the skeletal tissue of adult rats
- IV The effect of combined oophorectomy and prolonged prednisolone administration on the blood calcium level and the distribution of Ca^{45} between blood and bone in adult rats
- V The glycosaminoglycans of compact bone tissue in experimental osteoporosis induced by prednisolone treatment of oophorectomized rats or by calcium restriction

calcium from the body but that they are able to maintain calcium equilibrium by increasing the uptake of dietary calcium from the intestine (Hironaka et al 1960)

Despite numerous studies on the adaptation by the rat to a restricted calcium intake the reaction of the skeleton to long term calcium deficiency is still poorly understood. Young growing rats have been reported to develop osteoporosis on a diet deficient in calcium but adequate in vitamin D (Crawford et al 1957 Harrison and Fraser 1960). However it has also been reported that growing rats fed a similar diet deficient only in calcium develop skeletal changes typical of rickets (Park et al 1922 Hess 1929 Engfeldt et al 1962). The experiments of Gershon Cohen et al (1962) suggest that a low calcium diet results in rachitic lesions in the young growing rat but that in adults the condition is transformed into osteoporosis. A weaned rat placed on a low calcium diet shows signs of rickets for a short time only. The rickets changes thereafter into osteoporosis without a change of diet (McClendon and Blaustein 1965).

The mature rat is generally considered to be resistant to the development of osteoporosis on receiving a low calcium diet because of its effective adaptation to a low calcium intake. It has been stated that a marked adaptation viz a distinctly increased efficiency of calcium absorption which compensates fully for any previous loss will occur only when the old rats have suffered a substantial loss of calcium from the skeleton. This delayed reaction might be expressed as a considerable period of latency. In principle this finding agrees with observations in man (Nicolaysen et al 1953). However there appears to have been no previous investigation confined to a study of the effect of prolonged calcium deficiency on the skeleton of the adult rat and the pathomechanisms responsible for the skeletal changes induced by such treatment. It was considered that such an investigation would provide valuable information concerning the relationship between calcium deficiency and the development of osteoporosis since the mechanisms involved in the adaptation to a restricted calcium intake seem to be similar for rats and humans.

The present investigation was undertaken with the aim of studying the response of the mature skeletal tissue to prolonged calcium restriction and of following the development of possible skeletal changes during different periods of maintained low calcium intake. This report concerns the composition and the histology of the skeletal tissue in one year old male rats maintained on a low calcium diet for periods of time varying from 1 week up to 1 year.

INTRODUCTION

The onset of generalized osteoporosis in humans has been related to a low intake or malabsorption of calcium (Nordin 1960, 1961, 1962 Nordin *et al* 1964 Spencer *et al* 1964). It has also been stated that in the generalized osteoporoses the bone mass is reduced because of the calcium needs of the organism (Heaney 1965). In human volunteers it has been shown by Malm (1958) that a negative calcium balance can be induced by changing from a normal to a low calcium intake. In the great majority of the subjects, adaptation took place and the balance became less negative. In a few subjects however there was a failure to adapt to the low calcium intake even after long periods of observation. In these subjects the persisting negative calcium balance eventually resulted in osteoporosis.

The relationship between calcium retention and body stores of calcium has been studied extensively in the rat. In young growing animals a previous low intake of calcium increases the retention of calcium in a subsequent period on a high calcium diet (Fairbanks and Mitchell 1936 Rottensten 1938 Nicolaysen 1943, Henry and Kon 1947 and 1953). In old rats also the absorption of calcium has been found to be definitely increased after prolonged calcium restriction (Henry and Kon 1953 Nicolaysen *et al* 1953). However experiments by Henry *et al* (1960) indicated that old rats fed a low calcium diet need a minimum of 4 months to adapt themselves to the low calcium intake and that this period of adaptation is longer for old than for young rats. In old rats a slow reduction of the absorption efficiency was observed by Kane *et al* (1949) while no change in the calcium metabolism with age was indicated by the findings of Henry and Kon (1953) and Nicolaysen (1956). Hansard and Crowder (1957) found that the true digestibility of dietary calcium by rats declined from 41 % at 48 to 72 weeks of age to 24 % at 106 weeks while the requirement for maintenance approximately doubled. It has also been reported that aged rats (22 to 32 months compared to 10 to 12 months) are subject to a greater loss of

Chemical analyses showed that the diet contained 0.09 per cent Ca and 0.55 per cent P¹. The Ca/P ratio was 1.6:1. The diet was supplied with an adequate amount of vitamin D. All animals were given their diet and deionized water *ad libitum*. The daily calcium intake was estimated at 18–20 mg per animal. Groups of 5 rats each were kept on this regimen for different periods of time: in the short term series ten groups for 1 to 16 weeks and in the long term series six groups for 6 to 12 months. In the short term series another group of 5 animals was fed the above described test diet supplemented with 4% CaCO₃; this diet thus containing a total amount of 1.7 per cent Ca and 0.55 per cent P. The Ca/P ratio was 1.04. This diet and tap water were given *ad libitum* for 16 weeks and the daily calcium intake of these animals was estimated at 340–360 mg.

Control animals

In the short term series one group of 5 rats received a normal laboratory ration² containing 1.0 per cent Ca and 0.75 per cent P for 16 weeks. The Ca/P ratio was 1.075. Diet and tap water were given *ad libitum*. The daily calcium intake of the rats belonging to this group was estimated at 200–220 mg. In the long term series one control group of 5 animals was fed the normal laboratory ration and tap water for 4 weeks in order to accustom the animals to the laboratory routine. These animals were stated to be approximately 20 months old when delivered to the laboratory.

Without access to direct sunlight all the animals were housed five to each cage at a temperature of 18–20°C. The cages were large enough to allow the animals to move about freely. No coprophagy was observed. The series were planned so that all the animals within each series were sacrificed at the same time. This was performed by bleeding them to death from the femoral artery under ether anaesthesia. After sacrifice the animal bodies were kept in the deep freezer at –20°C pending the subsequent preparations.

Body weight

In all animals the initial and the final body weight was recorded. In addition all the animals of the short term series were weighed weekly.

¹ Here and in the following text the figures calculated on a dry weight basis are given.

² Ewos Co. Sodertälje, Sweden.

EXPERIMENTAL

A total number of 95 adult male rats of the Sprague Dawley strain¹ were divided into two experimental series. Sixty animals comprised a short term and thirty five animals a long term series. Apart from the duration of the test diet both series were treated identically. All animals except the controls of the long term series (see page 21), were stated to 12 to 12½ months old at the start of the experiment. The mean initial body weights of the animals of the two series were 499.0 ± 5.2 and 501.8 ± 9.2 grams respectively. All animals had been bred on a standard laboratory ration containing on a dry weight basis, 1.4 per cent Ca and 1.2 per cent P and adequate amounts of vitamin D.

Experimental animals

All the experimental animals were fed the low calcium diet of General Biochemical Inc. Chagrin Falls, Ohio. This diet has the following composition (GBI Bulletin D 15)

<i>Ingredients</i>	<i>Composition</i>
Whole Dried Egg (ether extracted)	27.0 %
Sucrose	10.0
Lard	10.0
Dried Yeast	7.0
Cod Liver Oil ²	2.0
Starch	40.0
Salt mix	4.0
<i>Salt mix</i>	<i>Gms/100 lbs</i>
Ferric citrate	29.462
Magnesium chloride	855.122
Manganous sulfate	414
Potassium alum	190
Potassium chloride	355.491
Potassium citrate	371.976
Potassium iodide	0.85
Potassium sulfate	37.620
Sodium chloride	164.430
Sodium fluoride	1.048

² Vitamin D₃ 120,600 I.U./100 g diet which was protected against daylight

Hydroxyproline determinations

The hydroxyproline content of the whole third metacarpal bone including bone marrow and articular cartilages was determined in both series by the method of *Newman and Logan (1950)*. The bone was carefully freed of soft tissues and periosseum. All bones within each series were dried simultaneously at 48° C for 24 hours and were then weighed in weighing containers. Protein hydrolysates were prepared by autoclaving the whole bone with 0.5 ml of 6 N hydrochloric acid in sealed tubes for 10 hours at 100° C. A hydrolysis curve showed maximum hydroxyproline values after 6 hours and there was no decrease even after 21 hours hydrolysis. Duplicate determinations were performed throughout and average values were used. The coefficient of variation for these analyses was 2.0 per cent.

The gross bone density of the humerus

The density of the whole bone including bone marrow and articular cartilage, was determined according to *Robinson and Elliott (1957)*. The right humerus of the animals of the two series was carefully dissected free from surrounding soft tissues and periosteum. All bones within each series were soaked simultaneously in deionized water at 4° C for 16 hours. Each bone was then suspended on a fine wire attached to the condyles and weighed while submerged in water at room temperature. This was the weight of the hydrated whole bone submerged in water. All bones of each series were then dried simultaneously at 105° C for 16 hours and using weighing containers the air dried weight was recorded. The density of the dried whole bone was calculated by dividing the dry weight of the bone by the weight of water displaced by the dry bone volume.

Preparation of undecalcified sections

The two proximal tail vertebrae of each animal of the long term series and one metacarpal bone from some of the animals of the short term series were freed of most of the surrounding soft tissues and then fixed and dehydrated in 6 changes of 96 per cent alcohol for 6 days. The specimens were then placed in unpolymerized washed methyl methacrylate with the addition of a catalyst prepared as described by *Jowsey et al (1965)*. The specimens were embedded in glass bottles with semipolymerized monomer for one week and polymerization was then completed in an oven maintained at 37° C. The glass bottle was then

Radiographs

At the start of the experiment each animal was examined radiologically under ether anaesthesia and at the end of the experiment this examination was repeated. Each rat was placed with the spinal column and the extremities fixed directly on an X ray film and the same exposure conditions film and developer were used throughout.

Measurement of the cortical thickness in the mid shaft of the femur

This examination was performed on all animals of the long term series. The whole femur was dissected free from soft tissues and periosteum and its length from the top of the greater trochanter to the most distal point of the femoral condyles was measured with a caliper. A fine bandsaw was then used to divide the bone in the middle ± 0.5 mm of the diaphysis perpendicularly to the long axis of the diaphysis. With the aid of a caliper the internal and external transverse diameters were measured at the four cut surfaces obtained from the two divided femora of each animal. The cortical thickness at this point was calculated as the difference between the external and internal diameters and with an accuracy of 0.05 mm. Average values were used. This figure was divided by the mean value for the external transverse diameter of the shaft at the same level and this fraction was multiplied by 100. In this way the femur score was calculated according to Barnett and Nordin (1960).

Ash determinations

The ash content of the whole tibia including bone marrow and articular cartilages was determined in both experimental series as follows. After careful dissection from soft tissues and periosteum the bone was placed in a weighing container and the wet weight was immediately recorded in a Mettler balance with an accuracy of 0.05 mg. All bones within each series were thereupon ashed simultaneously in a muffle furnace at 700°C for 16 hours and the weight of the ashes was then recorded. The ash content was expressed as per cent of the wet weight. In the short term series the ash contents of both tibiae were determined and average values recorded. As no statistically significant difference between the ash contents of the right and the left tibiae was found only the right tibia was used in the long term series.

PW 1009 apparatus provided with a copper anode and a nickel window the X ray tube operating with 20 kV and 20 mA. After an exposure time of 15 minutes the pla es were developed for five minutes in Kodak D 158 washed and fixed in a conventional acid fixative Longitudinal sections of metacarpal bones in the short term series were ground first on an oscillating grinder then by hand and microradiographs were prepared as described above

Preparation of decalcified sections

The fourth metacarpal bone of all the rats of the short term series and the third tail vertebra of those of the long term series were fixed in 10 per cent neutral formaldehyde for 24 hours and then decalcified for 12-14 days in a mixture of equal parts of monosodium citrate (20%) and formic acid (44%). The specimens were then immersed in 5 per cent disodium sulphate for twenty four hours washed with water for twenty four hours and dehydrated by successively immersing in 70, 90 per cent and absolute alcohol (2 changes). Finally the specimens were immersed first in methyl benzoate and then in xylol and embedded in paraffin Five μ thick longitudinal sections of the metacarpal bones and cross sections of the vertebrae were cut and stained with Ehrlich's haematoxylin and eosin and in addition, with azocarmine G. Sections from the vertebrae were also stained with an 0.5 per cent solution of toluidine blue in phthalate at pH 4.4 as described by Belanger and Hartnett (1960)

Statistical treatment of data

For the computation an analysis of variance with one way lay out according to Scheffe (1961) was used. The hypothesis of no difference between groups was tested with a 5 per cent significance level. Significant contrasts between groups were tested at the same significance level according to Scheffe (1961). For computation of the data obtained from the one group fed the test diet enriched with calcium Student's *t* test was used according to Brownlee (1965) and with a significance level of 5 per cent.

¹ In the following text the term "significant" will stand for statistically significant

broken and the excess methacrylate was trimmed off with a bandsaw. For the subsequent examinations of the vertebrae, the plastic blocks were sawn into slices approximately 0.5 mm thick and exactly perpendicular to the long axis of the vertebra while the metacarpal bones were ground directly as described below.

Tetracycline labelling

All animals of the long term series were labelled with chlortetracycline (Aureomycin[®] Lederle) in two doses of 20 mg per kg body weight administered by intraperitoneal injection 10 and 20 days before sacrifice. Approximately 60 μ thick undecalcified methacrylate embedded cross sections from the second tail vertebra were mounted under coverslips in fluorescence free balsam (Permount) and examined in a Zeiss fluorescence microscope fitted with an UV light source (High Pressure Vacuum lamp HBO 200, exciter filters UG 2 and UG 5, barrier filters 65 and 41).

Quantitation of the amount of vertebral bone

Quantitation of the amount of bone present in a standard area was performed in the long term series as follows. Undecalcified sections embedded in methacrylate from the first tail vertebra were ground first on an oscillating grinder then by hand to a thickness of approximately 50 μ . Only sections containing most of the transverse processes were studied; these were examined unstained with the aid of an integrating eye piece (Zeiss I) as described by Wagner (1965). The number of vertebral bone hits of 200 points was determined with the point network exactly in the centre of the section at a linear magnification of 30 x; the accuracy was found to be more than 95 per cent.

Microradiographs

Microradiographs were prepared from the animals of the long term series as follows. Undecalcified cross sections embedded in methacrylate from the second tail vertebra were ground on a Knuth Rotor grinder to a thickness of approximately 60 μ . Silicon Carbide papers Nos 220 and 600 and water as a lubricant being used. The sections were then placed in direct contact with a fine grain emulsion (Kodak MR plates) and were radiographed in a Philips

Calcium enriched diet for 16 weeks						

Table 1 a. The initial and final body weights of the rats fed the normal laboratory ration the low calcium diet and the calcium enriched diet
(S.E.M. = standard error of the mean)

RESULTS

Six deaths occurred among the whole material five among the experimental animals in the long term series and one in the short term series all probably due to advanced age. These animals were excluded. The remaining animals were in good health.

Body weights (Fig. 1 Table 1 a b)

The rats fed the normal laboratory ration increased their body weight by almost 10 per cent during the first 7 weeks of observation. From then on and until the 16th week the body weight remained unchanged. In the animals fed the low calcium diet the body weight increased by almost 30 per cent during the first 7 weeks. Subsequently and up to the end of the 16th week no significant change was noted. The animals fed the low calcium test diet supplemented with

Fig. 1 Body weight change in per cent of the initial weight in the three groups of rats fed the normal laboratory ration (uninterrupted line) the low calcium diet (broken dotted line) and the calcium enriched diet (broken line) for 16 weeks. The bars represent the standard error of the mean.

Femur length

The femur length in the long term series showed no significant difference between the control group and the groups of animals fed the low calcium diet.

Radiographs

Radiological examination revealed that the epiphyseal zones of the long bones were closed in all animals. In some animals distributed at random among the whole material the remnants of the epiphyseal zones were recognized as a sclerotic line. In none of the animals maintained on a low calcium diet for 1 to 16 weeks was any notable change observed on radiographs taken at the start and at the end of the experimental period. On the other hand all animals fed the low calcium diet for 6 months and longer showed a slight but definite reduction of the cortical thickness of the tubular bones and the pelvis and decreased density of the trabecular pattern in the metaphyses and in the tail vertebrae.

The cortical thickness in the mid shaft of the femur (Table 2)

Direct measurement of the cortical thickness was performed in the long term series and revealed significantly lower values for the "femur score" in all the six groups of rats fed the low calcium diet for 6 to 12 months compared with the control group. The lower values for the cortical thickness corresponded to higher values for the internal transverse diameter while the external diameter showed no significant difference.

The ash content of the whole tibia (Fig. 2 Table 3)

The ash contents of the tibiae of the rats fed the low calcium diet for 1 to 12 weeks showed no significant difference from those of the rats fed the normal laboratory ration. Significantly lower values decreasing with time were obtained in the eight groups of rats kept on a low calcium intake for 14 weeks to one year. The decrease amounted to 6.2 % after 16 weeks of calcium restriction and 13.3 % after 12 months. The group of rats fed the diet enriched with calcium for 16 weeks showed slightly higher values than those of the group fed the normal laboratory ration for 16 weeks. This difference was not significant.

calcium showed an increase in their initial body weight by approximately 20 per cent during the first 5 weeks from that time onwards and until the end of the 16th week it remained unchanged (Fig 1) All rats given the test diet showed an appreciable increase in their subcutaneous and peritoneal fat tissue This was more pronounced in the animals fed the low calcium diet than in those for which this diet was enriched with calcium The final body weight showed no significant difference in the groups of rats fed the low calcium diet for 5 weeks up to 1 year (Table 1 a, b)

Table 5 The gross bone density of the humerus in rats fed the normal laboratory ration the low calcium diet and the calcium enriched diet

The percentage of vertebral bone loss (Table 6)

This was examined in the long term series. The six groups of animals maintained on a low calcium diet for 6 to 12 months showed significantly lower values than the control group.

Microradiography

Microradiographs of undecalcified vertebral cross sections showed that in the normal control rats the cortical and trabecular bone was quite evenly mineralized

The gross bone density of the humerus (Fig 4, Table 5)

The values obtained from the rats fed the low calcium diet for 1 to 16 weeks showed no consistent changes with time during the period of restricted calcium intake, but only a small intergroup variation and the statistical analysis revealed no significant differences. The six groups of rats kept on a restricted calcium intake for 6 to 12 months showed significantly lower values than the normal controls. The group of rats fed the calcium enriched diet for 16 weeks showed slightly higher values than the groups fed the normal laboratory ration. This difference was significant. Similar values were obtained for the two control groups.

Table 6 The vertebral bone mass calculated as percentage bone hits in rats fed the normal laboratory ration and the low calcium diet

(Fig. 5) The bone had a non lamellar (woven) appearance as described by Enlow (1963). No secondary osteones or resorption cavities were observed. In the animals maintained on a low calcium intake for 6 to 12 months the microradiographs had a similar appearance to those in the control group with the exception that the bone trabeculae were considerably thinner (Figs. 6 and 7). There was no difference in the degree of mineralization and both the cortical and the trabecular bone were as evenly mineralized as in the control animals. No resorption cavities were found. Microradiographs from longitudinal sections of the metacarpal bone in the short term series showed that the bone was evenly mineralized and that the epiphyseal zones were closed.

Histological observations

In the short term series decalcified longitudinal sections from the metacarpal bone of each animal were stained with haematoxylin eosin and azocarmine G respectively. In all the animals the epiphyseal zones were closed. The sections stained with haematoxylin eosin showed that in the control group the diaphysis contained mostly small osteocytes. Osteocytes with enlarged spherical lacunae were located approximately midway between the border of the central marrow cavity and the periosteum. Occasionally the lacunae in that area were empty.

no change in the staining properties was observed. The slightly basophilic areas did not differ from those in the control animals. The osteoid tissue was very scanty in the normal animals. No increase in the amount of osteoid tissue was observed in the calcium deficient animals. Neither was any difference observed in the amount of fibrous tissue associated with bone.

In the long term series decalcified cross sections of the vertebrae were stained with toluidine blue at pH 4.4 and in addition with haematoxylin-eosin and azocarmine G. In the different animals sections were cut from parts of the vertebra chosen at random. In each animal all the sections were cut from the same part of the vertebra allowing adjacent sections to be examined after different staining procedures. The cortical bone contained mostly small osteocytes but larger osteocytes were also found especially midway between the marrow cavity and the periosteum. The trabecular bone also contained small osteocytes and occasionally slightly larger ones. The cytoplasm the immediate border of

Fig. 2 Photomicrograph of vertebral cortical bone from a normal adult rat. A variety of osteocyte and also empty lacunae can be seen. Haematoxylin-eosin (x50).

Fig. 7 A detail of the microradiograph shown in fig. 6 The bone is evenly mineralized and there is no difference from normal in the degree of mineralization of the remaining bone tissue ($\times 100$)

of cells and had become filled with an amorphous substance. The immediate border of the osteocyte lacunae and the processes of the osteocytes were slightly basophilic. In the metaphyseal bone trabeculae slightly basophilic areas were seen. These areas were located either centrally or peripherally in a trabecula and frequently extended to its surface. Occasionally small scattered irregular areas which were slightly basophilic were observed in the cortex.

Histological sections from rats fed the low calcium diet for 1 to 16 weeks showed a similar appearance to those from the normal control animals. In all sections osteoblasts and osteoclasts were scanty. In fact no osteoclasts were observed either in the normal controls or in the animals fed the low calcium diet. The osteocytes had the same appearance as in the control animals and

areas were located in the trabecular bone and were observed most frequently in the metaphyseal regions. Nearer the mid portion of the vertebra the basophilic areas decreased in frequency. The basophilic areas were located in the spaces intervening between parallel fibered bone (Fig 10) and were metachromatic with toluidine blue (Fig 11). No difference in the staining properties of these areas was observed between normal animals and osteoporotic animals fed the low calcium diet for 6 to 12 months (Figs 12—14).

Fluorescence microscopy

In the normal animals fluorescence of newly formed bone was observed mainly on the trabecular surfaces (Fig 15) and on the surfaces of bone canals. Only parts of the trabecular surfaces were fluorescent while others were not. Despite the time interval of 10 days between the two administered doses there was as a rule only one fluorescent line to be observed. Occasionally double

the osteocyte lacunae and the processes of the osteocytes were slightly basophilic with haematoxylin eosin and metachromatic with toluidine blue. Lacunae empty of cells were occasionally found especially in the cortical bone (Fig 8). Some of these lacunae were filled with an amorphous substance which was metachromatic with toluidine blue stain. The osteocytes and the lacunae had a similar appearance in normal and experimental animals. The frequency of osteoblasts and osteoclasts was very low in the normal control animals and no increase was found in the calcium deficient osteoporotic animals. The sections stained with haematoxylin eosin or azocarmine G showed that the amount of osteoid tissue in the control animals was very small. No increase of the osteoid tissue was observed in the animals maintained on a prolonged low calcium diet. As in the tubular bone, areas which showed slightly basophilic staining with haematoxylin eosin were also found in the vertebral sections (Fig 9). These

Fig. 15 Fluorophotomicrograph showing labelling of a vertebral bone trabecula in a normal rat. Despite the time interval of 10 days between the two administered doses of chlortetracycline there is only one fluorescent line indicating a relatively low rate of new bone formation (x400).

rats kept on a low calcium intake were given a diet containing 0.09 per cent calcium and adequate amounts of phosphorus and vitamin D. The prevailing experimental conditions were therefore sufficient to bring the animals into a negative calcium balance. In a negative calcium balance the difference between calcium intake and output is evidently taken from the skeleton. In the ten groups of animals maintained on a low calcium intake for 1 to 16 weeks no change was observed in the roentgenological appearance of the skeleton and the density of the whole bone. Neither the hydroxyproline content nor the ash content of whole bones showed any significant changes during the first 12 and 14 weeks of calcium restriction. Not until after 14 weeks on a restricted calcium intake was a definite reduction in bone mass, i.e. a reduction of both the mineral and organic components as determined by the measurement of the contents of ash and hydroxyproline of whole bones observed in the old rats used in the present study. This finding supports the observations by Henry *et al.* (1960) that old rats kept on a similar low calcium diet remain in negative calcium balance for at least 4 months. In the present study a reduction of both the trabecular and the cortical bone resulting in a decrease in the density of the whole bone was found on X-ray examination by direct measurement of the cortical thickness in the mid shaft of the femur, i.e. "femur score" and in the percentage of vertebral bone "cuts". The reduction in the ash and the hydroxyproline contents of whole bones indicates a concomitant reduction of both the mineral and the collagen component of the skeletal tissue. Thus during the long term negative calcium balance induced by a restricted calcium intake in this experiment, mobilization of skeletal calcium occurred with a concomitant breakdown of organic bone matrix.

The bone composition of the rats in the group fed the test diet enriched with calcium for 16 weeks suggests an increase in the degree of mineralization compared with that of the animals fed the normal laboratory ration for the same period of time. Thus there was a significant increase in gross bone density compared with that of the normal controls. The observed increased ash content together with a decrease in the percentage hydroxyproline content of whole bones suggests an increased degree of mineralization of the bone collagen. This is further supported by the decreased retention of intraperitoneally administered Ca^{45} found in the same animals in a subsequent study (Larsson 1969).

It has been suggested from observations made in calcium balance studies on old rats that a considerable calcium deprivation by 5 per cent or more of the total body calcium is followed by a distinct, compensatory increase of the calcium absorption which continues with high efficiency until the total loss

fluorescent lines were found. The distance between the lines was quite short, indicating a relatively low rate of new bone formation.

In the osteoporotic animals fed the low calcium diet for 6 to 12 months the tetracycline fluorescent micrographs had a similar appearance to those in the normal control animals (Fig. 16). No difference in the degree of trabecular labelling was observed. Only occasionally were double fluorescent lines found and the distance between the lines was not apparently different from that in the control animals. The bone canals showed the same degree of labelling as in the normal rats. Both in the normal and in the calcium deficient rats the fluorescent uptake was highest in the metaphyseal regions of the vertebra.

DISCUSSION

The present study is concerned with the reaction of the well mineralized skeleton of one year old fully grown rats to a restricted calcium intake. The preliminary feeding induces different degrees of saturation of the calcium stores (Fairbanks and Mitchell 1936) and a normal calcium intake is necessary for the growth of all the tissues including bone, whether other conditions necessary for calcification are present or not (Carttar *et al* 1950, Toothill and Hosking 1968). The animals used in the present investigation had been bred on an optimum intake of calcium, phosphorus and vitamin D and rats with a mature skeleton were used in order to eliminate the interference of skeletal growth with the skeletal response of the treatment. The fact that the body weight of the control animals remained almost unchanged during the period of observation in combination with the absence of any difference in length of the bones strongly suggests that the skeletal growth of the animals used was completed at the start of the experiment. This is further supported by the observation that the uptake of radioactive calcium in bones of rats diminishes rapidly from the age of 3 to 6 months and then decreases very little with age in accordance with the growth rate (Bohr 1968). By histological examination it has been found that the epiphyseal cartilages are inactive in aged rats (El Maraghi *et al* 1965). This observation was confirmed by the examinations performed in the present study.

Old rats need approximately 0.5 per cent calcium in the diet to maintain calcium equilibrium (Henry and Kon 1947). In the present investigation the

showing basophilia with haematoxylin eosin are normally present in the metaphyseal bone in the rat some investigators have recognized the association of similar areas with resorption (Ruth 1954 1961) Also in the old rats used in the present investigation basophilic areas were found in the bone trabeculae of the metaphysis of the vertebrae Examination of decalcified sections stained with haematoxylin eosin azocarmine G or toluidine blue at pH 4 indicated that these areas consisted of intercellular substance probably containing acid mucopolysaccharides extending from the epiphysis into the bone trabeculae The staining properties of these areas were similar in osteoporotic animals and normal controls No changes were observed which could be related to the osteoporotic process Intensified staining of mucopolysaccharides has been reported in areas where bone removal is taking place (Heller Steenberg 1951 Engel 1952) While in those experiments young growing animals were studied under conditions of induced rapid bone resorption no such changes were observed in the adult animals used in the present investigation

Osteolysis i.e. osteocytic resorption of cells surrounded by matrix that contains mucopolysaccharides and induces toluidine blue metachromasia has been observed after the institution of low calcium or high phosphorus diets (Belanger 1963) Osteoclastic resorption has been considered to be of far less importance than osteolysis in both normal bone remodelling and in accelerated resorption as e.g. in hyperparathyroidism (Belanger et al 1963 Belanger and Robichon 1964 Gries 1966 Brown et al 1966) In the present investigation no increase in metachromasia around osteocytes was observed in the calcium deficient osteoporotic animals compared with the normal controls The appearance of increased osteolysis is probably dependent upon the degree of calcium deficiency induced

While young rats are reported to develop skeletal changes typical of rickets upon specific calcium deficiency (Park et al 1922 Hess 1929 Carttar et al 1950 Engfeldt et al 1962 Gershon Cohen et al 1967 McClendon and Blaustein 1965) no signs of rickets or osteomalacia were found at any stage of calcium deficiency by the histological microradiographical and tetracycline labelling studies performed in the present investigation Osteoporotic bone changes reported in young calcium deficient rats by Crawford et al (1957) and Harrison and Fraser (1960) are apparently late changes secondary to calcium-deficiency rickets and disturbed skeletal growth (Gershon Cohen et al 1962 McClendon and Blaustein 1965) No conclusions can be drawn from those experiments regarding the maintenance of the mature skeleton and the development of osteoporosis which characteristically is a disease of the adult individual

in the calcium deprivation period has been compensated (*Nicolaysen et al* 1953). In the present investigation the maximum decrease in the ash content of the whole bone amounted to 13.3 per cent and was found in the group of rats maintained on a low calcium intake for 12 months. After the 14th week of restricted calcium intake there was a successive reduction in the ash content of the tibia. This finding is not consistent with a delayed increase in calcium absorption and calcium equilibrium despite continuous low calcium intake. A further reduction in bone mass would not have been expected otherwise in the groups of rats kept on the low calcium diet for the longer periods of time i.e. 10 to 12 months. It is thus, of great interest that, contrary to the suggestion of *Nicolaysen et al* (1953) no tendency to a restitution of the bone tissue lost was observed in the groups of rats maintained on prolonged calcium restriction. The continuous loss of bone mineral observed in the present investigation indicates that the old rats failed to adapt to the restricted calcium intake during the experimental period of one year. Since the variability in calcium absorption studies is considerable with a reported coefficient of variation of approximately 25 (*Nicolaysen et al* 1953) a slight continuous calcium loss from the skeleton would be difficult to determine with such techniques.

With the tetracycline double labelling procedure no difference in the amount of bone surfaces showing new bone formation was observed in the normal control animals and in the osteoporotic rats fed the low calcium diet for 6 to 12 months. Neither was any difference in the degree of mineralization noted on microradiographs of undecalcified vertebral bone sections. There were further no cellular differences from the normal in decalcified histological sections of bone in the different experimental animals. It is concluded therefore that the bone changes induced in the present investigation are in accordance with those of typical osteoporosis as described by *Collins* (1966).

In many earlier animal experiments purporting to demonstrate the effect of calcium deprivation inanition and therefore protein calorie deficiency also occurred (see *Platt et al* 1961 *El Maraghi et al* 1965). This dual aetiology was eliminated in the present experiment in which the animals were kept on a high calorie low calcium diet. The possibility of bone atrophy due to inactivity was also excluded.

Various morphological changes of the bone tissue i.e. basophilia of the bone trabeculae fibrosis and increased clasmotocytic activity have been reported to be characteristic of osteoporosis in rats (*McClendon and Blaustein* 1965). However such changes appear to be more typical of osteitis fibrosa than of osteoporosis and were not observed in the present investigation. Although areas

by *Jousey and Raisz* (1968) was apparently transient since in cats fed the low calcium diet for 13 months the osteoid borders, although highly increased in frequency were of normal width. The decrease in resorption but not in formation observed in such animals treated with a high calcium diet for 1 month suggested that the bone changes induced by the low calcium diet could be reversed. In adult dogs maintained on a low calcium high phosphorus diet, bone lesions as in osteitis fibrosa have recently been reported (*Satille andbrook* 1968). Histological examination of decalcified bone sections showed the presence of numerous osteoblasts with the appearance of resorption cavities and further osteoblasts and osteoid tissue covering the surfaces of cancellous bone. Despite the definitely increased amount of osteoid tissue the calcium accretion rate by bone was normal (*Satille andbrook* 1968). This condition suggesting qualitative changes in the bone tissue was called nutritional hyperparathyroidism.

Although prolonged deficiency or malabsorption of calcium has been related to the onset of osteoporosis in humans (*Nordin* 1960 1961 1962 1964) and calcium therapy is widely used in the treatment of the condition the relation of calcium deficiency to osteoporosis is not clear (*Dent and Watson* 1966). Of primary importance in this connection is the observation by *Malm* (1958) that a negative calcium balance prevails in human volunteers for a relatively long time after the institution of a low calcium intake. In a review of the literature it has been stated that osteoporosis can be produced in adult animals by a negative calcium balance usually induced by low calcium diets (*Nordin* 1960). However it was only young growing animals that were studied in these experiments. It is now established that the reaction of the growing skeleton is quite different to that of the mature skeleton. In young rats the bone lesions correspond to those in typical rickets. When there is a rapid reduction in bone mass due to pronounced calcium deficiency osteitis fibrosa or osteomalacia will occur both in growing and in mature animals. In the present investigation the development of osteoporosis is described in mature rats placed on a low calcium diet for varying periods of time from the age of one year. Results of calcium balance studies indicate that the general principle of the adaptation of calcium absorption in old rats can be applied also to other species (*Nicolaysen et al* 1953). The results of the present investigation suggest therefore that prolonged calcium restriction might contribute to the onset of symptomatic osteoporosis in adult humans also.

In lactating female rats a reduction of the bone tissue has been induced by instituting a low calcium diet (Tomlin *et al* 1953, McClendon and Blaustein 1965) These changes were described as osteoporosis and could be reversed by the administration of tricalcium phosphate (McClendon and Blaustein 1965) However, the morphological criteria of osteoporosis used suggest that the condition induced was osteitis fibrosa rather than osteoporosis
